Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

PREFACE

The 4th edition of the *Manual of Cardiovascular Medicine* has been extensively updated and revised. New chapters on diabetes and the heart, pulmonary hypertension, cardiovascular manifestations of systemic disease, percutaneous management of structural heart disease, and troubleshooting ventricular assist devices have been added. Examples of key electrocardiographic tracings have been added as has a quick reference list of often needed formulae. Our aim has been to make this an easy-to-use, up-to-date, portable reference for all those involved in the management of cardiovascular disease. We have included current guidelines from the American Heart Association/American College of Cardiology and other national and international cardiovascular societies where appropriate. We appreciate the feedback we have received concerning prior editions and suggestions as to how to improve the book.

This manual has been written by the current and past fellows and staff of the Department of Cardiovascular Medicine, Cleveland Clinic. I wish to thank all those who contributed to this and previous editions, especially Eric Topol, coeditor in prior editions and now at Scripps, San Diego, and Steve Marso now at Mid America Heart Center, Kansas City, coeditor of the 1st edition. I wish to recognize the associate editors of this edition, Venu Menon and Tom Callahan, who are associate directors of the Cardiovascular Disease Training Program at Cleveland Clinic and who have done a superb job in helping edit the manual and keeping it topical. The guest editors, Willis M. Wu, Clay A. Cauthen, and Justin M. Dunn, are or have been Chief Fellows in the Cardiovascular Training Program at Cleveland Clinic and have done a fine job of ensuring that the contributions were on time and comprehensive. The section editors, Leslie Cho, Esther S.H. Kim, Richard A. Krasuski, and W.H. Wilson Tang, have done a great job in ensuring the quality and topicality of their sections.

I wish to thank Lois Adamski, the educational coordinator of the Cardiovascular Disease Training Program at Cleveland Clinic, for having anchored the program over many years. Fran DeStefano, Leanne Vandetty, and everyone at Wolters Kluwer have been wonderful to work with. I remain deeply indebted to John and Rosemary Brown for endowing a Chair in Cardiovascular Medicine that supports my academic activity and for their wonderful friendship. I have learned much over the years from my colleagues and fellows at the Department of Cardiovascular Medicine at Cleveland Clinic and from my surgical colleagues in the Heart and Vascular Institute, Cleveland Clinic, and I thank all of them for their collegiality and kindness. Finally, I wish to express my immense gratitude to my family: to my parents for instilling in me a thirst for knowledge and to my wife Mary without whose support, patience, and fortitude this and all other endeavors would have been impossible.

Brian P. Griffin, MD

SECTION I

Ischemic Heart Disease 1

Editor: Venu Menon

1 Acute Myocardial Infarction 2
Christopher M. Huff

2 Unstable Angina and Non–ST-Segment Elevation Myocardial Infarction 36
James E. Harvey

3 Complications of Acute Myocardial Infarction 60
Michael P. Brunner and Venu Menon

4 Cardiogenic Shock Complicating Acute Myocardial Infarction 77
Michael P. Brunner and Venu Menon

5 Post–Myocardial Infarction Risk Stratification and Management 86
Willis M. Wu and Venu Menon

6 Stable Angina 97
Amar Krishnaswamy and Samir R. Kapadia

7 Other Ischemic Syndromes: Silent Ischemia and Syndrome X 120
Gus Theodos

SECTION II

Heart Failure and Transplant 125

Editor: W.H. Wilson Tang

8 Heart Failure with Systolic Dysfunction 126
Michael A. Samara and W.H. Wilson Tang

9 Heart Failure with Preserved Ejection Fraction and Restrictive Cardiomyopathy 150
Evan Lau and W.H. Wilson Tang

10 Hypertrophic Cardiomyopathy 160
Anthony Hart and Eiran Z. Gorodeski

11 Myocarditis 176
Mosi K. Bennett and W.H. Wilson Tang

12 Nontransplantation Surgical Treatment for Chronic Heart Failure 187
Clay A. Cauthen, Gonzalo Gonzalez-Stawinski, and Mazen Hanna

13 Cardiac Transplantation 199
Peter Zimbwa

14 Pulmonary Hypertension 224
Praneet Kumar and W.H. Wilson Tang

SECTION III

Valvular Heart Disease 237

Editor: Brian P. Griffin

15 Aortic Valve Disease 238
Olcay Aksoy and Brian P. Griffin

16 Mitral Valve Disease 265
Amanda R. Vest and Brian P. Griffin

17 Tricuspid Valve Disease, Pulmonary Valve Disease, and Drug-Induced Valve Disease 295
Shikhar Agarwal and Brian P. Griffin

18 Prosthetic Heart Valves 308
João L. Cavalcante

19 Infective Endocarditis 327
Marwa A. Sabe and Brian P. Griffin

20 Rheumatic Fever 347
Chetan Vagesh Hampole

SECTION IV

Arrhythmias 357

Editor: Thomas D. Callahan

21 Tachyarrhythmias 358
Omeed Zardkoohi

22 Bradyarrhythmias, Atrioventricular Block, Asystole, and Pulseless Electrical Activity 390
Santosh S. Oommen

23 Sudden Cardiac Death 411
Edmond M. Cronin

24 Atrial Fibrillation 424
Edwin T. Zishiri and Thomas D. Callahan

SECTION V

Vascular and Pericardial Disease 445

Editor: Esther S.H. Kim

25 Venous Thromboembolism and Hypercoagulable States 446
Firas Al Solaiman and Esther S.H. Kim

26 Aortic Aneurysm and Aortic Dissection 459
Matthew C. Bunte and Maran Thamilarasan

CHAPTER 1

Christopher M. Huff

Acute Myocardial Infarction

I. EPIDEMIOLOGY. Acute myocardial infarction (MI) is the leading cause of death in North America and Europe. Each year, an estimated 785,000 Americans will sustain a new MI, and another 470,00 will have a recurrent MI. An American has an acute MI every 25 seconds, and someone dies of an MI every minute. In 2007, coronary heart disease caused one out of every six deaths. The incidence and mortality with acute MI have declined dramatically over the last 30 years, with the advent of the coronary care unit, fibrinolytic therapy, catheter-based reperfusion, and statin therapy. The aging of the population in advanced economies, as well as the global increased incidence of diabetes and obesity, will however, increase the sequelae of atherosclerotic coronary artery disease in the future (1).

II. PATHOPHYSIOLOGY. In most patients, coronary plaque rupture is the initiating event of acute MI. Rupture of the fibrous cap of a coronary atheroma exposes the underlying subendothelial matrix to formed elements of circulating blood, leading to activation of platelets, thrombin generation, and thrombus formation. Erosion of a coronary plaque without rupture can also lead to thrombus formation and is estimated to cause up to 25% of MIs. Acute coronary syndrome (ACS) is a dynamic process that involves cyclical transitioning among complete vessel occlusion, partial vessel occlusion, and reperfusion. Occlusive thrombus in the absence of significant collateral vessels most often results in acute ST-segment elevation myocardial infarction (STEMI). The pathophysiology of STEMI and non–ST-segment elevation myocardial infarction (NSTEMI) is similar, and this explains the substantial overlap in ACSs with regard to ultimate outcome, extent of necrosis, and mortality rates. The recognition of ST-segment elevation is particularly important because it generally mandates the need for emergent reperfusion therapy.

III. DEFINITION. A 2007 expert consensus document (2) redefined acute MI as the detection of a rise and/or fall in cardiac troponin with at least one value above the 99th percentile of the upper reference limit (URL) utilizing an assay with < 10% coefficient of variation at the level of detection, together with evidence of ischemia. Ischemia was defined as any symptom of ischemia, electrocardiographic changes suggestive of new ischemia, development of pathologic Q waves on electrocardiogram (ECG), or imaging evidence of infarction. Included in the definition were sudden cardiac death (SCD) with evidence of myocardial ischemia (new ST elevation, left bundle branch block [LBBB], or coronary thrombus) and biomarker elevation > 3× URL for post–percutaneous coronary intervention (PCI) patients or > 5× URL for post–coronary artery bypass grafting (post-CABG) patients. Documented stent thrombosis was recognized in this new definition as well (Table 1.1). Established MI was defined as any one criterion that satisfies the following: development of new pathologic Q waves on serial ECGs, imaging evidence of MI, or pathologic findings of healed or healing MI.

TABLE 1.1 Clinical Classification of Different Types of Myocardial Infarction

Type 1	Spontaneous MI related to ischemia from a coronary plaque rupture or dissection
Type 2	MI due to ischemia resulting from increased oxygen demand or decreased supply
Type 3	Sudden cardiac death with symptoms of ischemia, new ST elevation, or LBBB or coronary thrombus
Type 4a	MI associated with PCI
Type 4b	MI associated with stent thrombosis
Type 5	MI associated with CABG

CABG, coronary artery bypass grafting; LBBB, left bundle branch block; MI, myocardial infarction; PCI, percutaneous coronary intervention.

Adapted from Thygesen K, Alpert JS, White HD. Universal definition of myocardial infarction. *J Am Coll Cardiol.* 2007;50:2173–2175.

IV. CLINICAL DIAGNOSIS. In any patient with a clinical history of chest pain suspected to be of cardiac origin, an ECG should be obtained within 10 minutes of presentation and interpreted promptly to determine eligibility for reperfusion therapy. If the **ECG demonstrates acute ST-segment elevation or new LBBB, emergent reperfusion treatment with primary PCI or fibrinolysis is indicated**. During this evaluation period, a targeted medical history and physical examination should be performed. If the patient's history is compatible with cardiac ischemia and the ECG does not meet the criteria for reperfusion therapy, the patient may have unstable angina or NSTEMI. These syndromes are discussed in Chapter 2.

A. Signs and symptoms

1. The classic symptoms are severe, **crushing substernal chest pain** described as a squeezing or constricting sensation with frequent radiation to the left arm, often associated with an impending sense of doom. The discomfort is similar to that of angina pectoris, but it is typically more severe, of longer duration (usually > 20 minutes), and is not relieved with rest or nitroglycerin. Peak intensity is usually not instantaneous, as it would be with pulmonary embolism or aortic dissection.
   a. The chest discomfort may radiate to the neck, jaw, back, shoulder, right arm, and epigastrium. Pain in any of these locations without chest pain is possible. Myocardial ischemic pain localized to the epigastrium is often misdiagnosed as indigestion. Acute MI can occur without chest pain, especially among postoperative patients, the elderly, and those with diabetes mellitus.
   b. If the pain is sudden, radiates to the back, and is described as tearing or knife-like, aortic dissection should be considered.
2. Associated symptoms may include diaphoresis, dyspnea, fatigue, light-headedness, palpitations, acute confusion, indigestion, nausea, or vomiting. Gastrointestinal symptoms are especially common with inferior infarction.

B. Physical examination. In general, the physical examination does not add much to the diagnosis of acute MI. However, the examination is extremely important in excluding other diagnoses that may mimic acute MI, in risk stratification, in the diagnosis of impending heart failure, and in serving as a baseline examination to monitor for mechanical complications of acute MI that may develop.

1. **Risk stratification**, which aids in treatment decisions and counseling patients and families, is based in part on age, heart rate, and blood pressure and on the presence or absence of pulmonary edema and a third heart sound.
2. The **mechanical complications** of mitral regurgitation and ventricular septal defect are often heralded by a new systolic murmur (see Chapter 3). Early diagnosis of these complications relies on well-documented examination findings at baseline and during the hospital course.

V. DIFFERENTIAL DIAGNOSIS. The differential diagnosis of ST elevation includes conditions with comorbid ischemia such as acute aortic dissection involving the root, conditions with ST elevation but no ischemia such as left ventricular (LV) hypertrophy or early repolarization abnormality, and conditions with chest pain but no ischemia such as myopericarditis (Table 1.2). The most common differential diagnostic considerations are discussed in the following text.

A. Pericarditis. Chest pain that is worse when the person is supine and improves when the person is sitting upright or slightly forward is typical of pericarditis. Care must be taken in excluding acute MI, however, because pericarditis can complicate acute MI. The electrocardiographic abnormalities of acute pericarditis may also be confused with acute MI. Diffuse ST-segment elevation is the hallmark of acute pericarditis, but this finding may be seen in acute MI that involves the left main coronary artery or a large "wraparound" left anterior descending artery. PR-segment depression, peaked T waves, or electrocardiographic abnormalities out of proportion to the clinical scenario may favor the diagnosis of pericarditis. The ST-segment elevations in pericarditis are often concave, whereas the ST-segment elevations in acute MI are usually convex. Reciprocal ST depression does not occur in pericarditis, except in leads aVR and V_1. Early T-wave inversion is not a feature of acute pericarditis. Echocardiography may be useful, not in evaluating pericardial effusion, which may occur in either condition, but in documenting the lack of wall motion abnormalities in the setting of ongoing pain and ST elevation.

B. Myocarditis. As with pericarditis, the symptoms and electrocardiographic findings of myocarditis may be similar to those of acute MI. Echocardiography is less useful in differentiating this syndrome from acute MI, because segmental LV dysfunction may be encountered in either condition. A complete history often reveals a more insidious onset and associated viral syndrome with myocarditis.

TABLE 1.2 Differential Diagnostic Considerations for ST-Segment Elevation Myocardial Infarction

Comorbid ischemia	ST elevation but no ischemia	Chest pain but no ischemia
Aortic dissection	Early repolarization	Aortic dissection
Systemic arterial embolism	Left ventricular hypertrophy	Myopericarditis
Hypertensive crisis	Left bundle branch block	Pleuritis
Aortic stenosis	Hyperkalemia	Pulmonary embolism
Cocaine use	Brugada syndrome	Costochondritis
Arteritis		Gastrointestinal disorders

Adapted from Christofferson RD. Acute ST-elevation myocardial infarction. In: Shishehbor MH, Wang TH, Askari AT, et al., eds. *Management of the Patient in the Coronary Care Unit.* New York: Lippincott Williams & Wilkins; 2008.

C. **Acute aortic dissection.** Sharp, tearing chest pain that radiates through the chest to the back is typical of aortic dissection (see Chapter 26). This type of radiation pattern should be investigated thoroughly before administration of antithrombotic, antiplatelet, or fibrinolytic therapy. Proximal extension of the dissection into either coronary ostium can account for acute MI. A chest radiograph may reveal a widened mediastinum. Transthoracic echocardiography may reveal a dissection flap in the proximal ascending aorta. If it does not, a more definitive diagnosis should be obtained with transesophageal echocardiography (TEE), computerized tomography (CT), or magnetic resonance imaging (MRI).

D. **Pulmonary embolism.** Shortness of breath associated with pleuritic chest pain but without evidence of pulmonary edema suggests pulmonary embolism. Echocardiography helps to rule out wall motion abnormalities and may identify right ventricular (RV) dilatation and dysfunction in the setting of pulmonary embolism.

E. **Esophageal disorders.** Gastroesophageal reflux disease, esophageal motility disorders, and esophageal hyperalgesia can cause chest pain, the character of which is very similar to cardiac ischemic pain. These disorders can often coexist in patients with coronary disease, thereby complicating the diagnosis. A workup for coronary disease should precede evaluation of esophageal disorders. Symptoms that may be suggestive but not diagnostic of chest pain of an esophageal origin include postprandial symptoms, relief with antacids, and lack of radiation of pain.

F. **Acute cholecystitis** can mimic the symptoms and ECG findings of inferior acute MI, although the two can coexist. Tenderness in the right upper quadrant, fever, and an elevated leukocyte count favor cholecystitis, which can be diagnosed by means of hepatobiliary iminodiacetic acid (HIDA) scanning.

VI. LABORATORY EXAMINATION (Fig. 1.1)

A. **Troponins.** Troponin T and troponin I assays are particularly useful in the diagnosis and management of unstable angina and NSTEMI because of their high sensitivity, ability to be used and interpreted rapidly at bedside, and nearly universal availability. Currently, the lag time between occlusion and detectable elevations in serum levels limits their usefulness in the diagnosis of acute STEMI; however, the development of high-sensitivity troponin T assays may allow for more rapid detection of myocardial necrosis. Also, data have suggested that a single troponin T concentration measured 72 hours after acute MI may be predictive of MI size, independent of reperfusion (3). Troponin elevation in the absence of ischemic heart disease can be found in congestive heart failure (CHF), aortic dissection, hypertrophic cardiomyopathy, pulmonary embolism, acute neurologic disease, cardiac contusion, or drug toxicity.

B. **Creatine kinase (CK).** An elevated level of CK is rarely helpful in making the diagnosis of acute MI for a patient with ST-segment elevation. Because it usually takes 4 to 6 hours to see an appreciable rise in CK levels, an initial normal value does not exclude recent complete occlusion. CK and CK-MB (creatine kinase myocardial band) levels can be elevated in the presence of pericarditis and myocarditis, which may cause diffuse ST-segment elevation. CK levels are more helpful in gauging the size and timing of acute MI than in making the diagnosis. CK levels peak at 24 hours, but the peak CK level is believed to occur earlier among patients who undergo successful reperfusion. False-positive results of CK elevation occur in a variety of settings, including skeletal muscle disease or trauma (e.g., rhabdomyolysis).

C. **Myoglobin.** Damaged cardiac myocytes rapidly release this protein into the bloodstream. Peak levels occur between 1 and 4 hours, allowing for early diagnosis of acute MI. However, myoglobin lacks cardiac specificity, thereby limiting its clinical utility. Studies have indicated that it might play a role in risk stratification after reperfusion therapy (4).

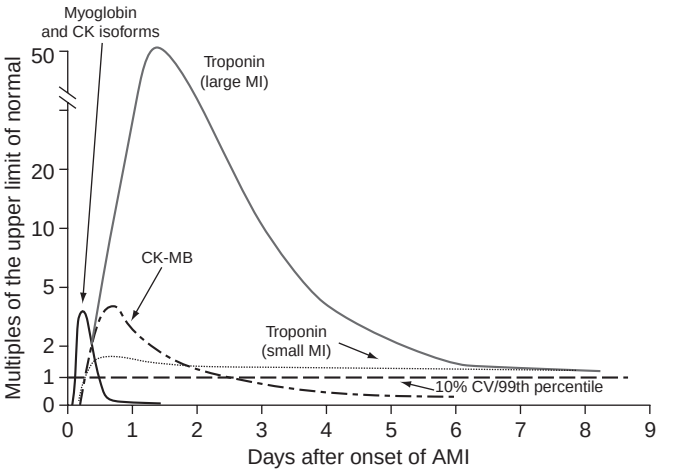

FIGURE 1.1 Timing of biomarker release after acute myocardial infarction. AMI, acute myocardial infarction; CK, creatine kinase; CK-MB, creatine kinase myocardial band; CV, coefficient of variation. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction—executive summary. *J Am Coll Cardiol.* 2007;50:652–726, with permission from Elsevier.)

VII. DIAGNOSTIC TESTING

A. Electrocardiography

1. **Definitive electrocardiographic diagnosis** of acute MI requires ST elevation of 1 mm or more in two or more contiguous leads, often with reciprocal ST depression in the contralateral leads. In leads V_2–V_3, 2 mm of ST elevation in men and 1.5 mm in women are required for accurate diagnosis.
2. **ECG subsets.** ST-segment elevations can be divided into subgroups that may be correlated with the infarction-related artery and risk of death. These five subgroups are listed in Table 1.3 and illustrated in Figure 1.2.
3. **Left bundle branch block**
   a. **New LBBB in the setting of symptoms consistent with acute MI** may indicate a large, anterior wall acute MI involving the proximal left anterior descending coronary artery and should be managed as acute STEMI.
   b. **In the absence of an old ECG or in the presence of LBBB at baseline**, the diagnosis of acute STEMI can be made with > 90% specificity on the basis of the criteria listed in Table 1.4 and illustrated in Figure 1.3.
   c. **Right bundle branch block (RBBB) may** complicate interpretation of ST elevation in leads V_1 through V_3. RBBB does not, however, obscure ST-segment elevation.

B. Echocardiography may be helpful in the evaluation of LBBB of undetermined duration in that the lack of regional wall motion abnormality in the presence of continuing symptoms makes the diagnosis of acute MI unlikely. It is worth noting that abnormal septal motion is often observed in the setting of LBBB even in the absence of ischemia.

TABLE 1.3 Acute Myocardial Infarction: Electrocardiogram Subsets and Correlated Infarct-Related Artery and Mortality

Category	Anatomy of occlusion	ECG findings	30-Day mortality rate (%)[a]	1-Year mortality rate (%)
1. Proximal LAD	Proximal to first septal perforator	ST↑ V_1–V_6, I, aVL and fascicular or bundle branch block	19.6	25.6
2. Mid-LAD	Proximal to large diagonal but distal to first septal perforator	ST↑ V_1–V_6, I, aVL	9.2	12.4
3. Distal LAD or diagonal	Distal to large diagonal or diagonal itself	ST↑ V_1–V_4, or I, aVL, V_5, V_6	6.8	10.2
4. Moderate to large inferior (posterior, lateral, right ventricular)	Proximal RCA or left circumflex	ST↑ II, III, aVF, and any of the following: (a) V_1, V_3R, V_4R (b) V_5, V_6 (c) R > S in V_1, V_2	6.4	8.4
5. Small inferior	Distal RCA or left circumflex branch	ST↑ II, III, aVF only	4.5	6.7

ECG, electrocardiogram; LAD, left anterior descending (coronary artery); ↑, increased; RCA, right coronary artery.

[a]Mortality rate based on GUSTO I cohort population in each of the 5 year categories, all receiving reperfusion therapy.

VIII. RISK STRATIFICATION. It is possible and useful to estimate the risk of death of a patient with acute MI. The estimate can aid in making treatment decisions and recommendations and in counseling patients and families. Five simple baseline parameters have been reported to account for > 90% of the prognostic information for 30-day mortality. These characteristics are given in descending order of importance: age, systolic blood pressure, Killip classification (Table 1.5), heart rate, and location of MI (Table 1.3, Fig. 1.2) (5). In addition, various risk models have been created to improve risk prediction.

A. The Thrombolysis in Myocardial Infarction (TIMI) risk score incorporates eight variables obtained from the history, physical examination, and ECG (Table 1.6). In patients treated with fibrinolysis, a TIMI score of 9 or greater predicts a 30-day mortality of approximately 35%. In patients with a TIMI score of 0 or 1, the 30-day mortality rate is < 2%. The strongest predictor of poor prognosis is advanced age (where age ≥ 75 years receives 3 points and age 65 to 74 years receives 2 points). Other variables that predict a poor prognosis include hypotension, Killip class II–IV at presentation, tachycardia, history of diabetes or hypertension, anterior ST elevation (also complete LBBB), low body weight, and a time to treatment of > 4 hours.

New York: Lippincott-Raven; 2002, with permission.)".

TABLE 1.4 Electrocardiographic Criteria for the Diagnosis of Acute Myocardial Infarction in the Presence of Left Bundle Branch Block

Criterion	Score[a]
ST-segment elevation ≥ 1 mm concordant with QRS	5
ST-segment depression ≥ 1 mm in leads V_1, V_2, or V_3	3
ST-segment elevation ≥ 5 mm discordant with QRS	2

[a]Point scores for each criterion met are added. Total point score of 3 yields ≥ 90% specificity and an 88% positive predictive value.

Adapted from Sgarbossa EB, Pinski SL, Barbagelata A, et al. Electrocardiographic diagnosis of evolving acute myocardial infarction in the presence of left bundle branch block. *N Engl J Med.* 1996;334:481–487.

B. The Global Registry of Acute Coronary Events (GRACE) score is used to predict in-hospital mortality in patients with ACS. Risk is calculated based on Killip class, heart rate, systolic blood pressure, creatinine level, age, presence or absence of cardiac arrest at admission, presence or absence of cardiac biomarkers, and ST-segment deviation. Patients with a score of ≤ 60 have a ≤ 0.2% probability of in-hospital mortality, whereas patients with a score of ≥ 250 have a ≥ 52% probability of in-hospital mortality.

IX. THERAPY

A. Prior to reperfusion

1. **Aspirin.** Immediate administration of aspirin is indicated for all patients with acute MI, unless there is a clear history of true aspirin allergy (not intolerance). Aspirin therapy conveys as much mortality benefit as streptokinase (SK), and the combination provides additive benefit (6). The dose should be four 81 mg chewable tablets (for more rapid absorption) or one 325 mg nonchewable tablet. If oral administration is not possible, a rectal suppository can be given. If true aspirin allergy is present, clopidogrel monotherapy is the best alternative. In STEMI patients who undergo PCI, aspirin should be continued indefinitely. According to the 2011 ACCF/AHA/SCAI PCI guidelines, after PCI it is reasonable to use 81 mg of aspirin as opposed to higher maintenance doses (16).
2. **Oxygen.** Supplemental oxygen by means of nasal cannula should be given to all patients with suspected MI. Administration through a face mask or endotracheal tube may be necessary for patients with severe pulmonary edema or cardiogenic shock.
3. **Nitroglycerin.** It is worthwhile to give sublingual nitroglycerin (0.4 mg) to determine whether the ST-segment elevation represents coronary artery spasm while arrangements for reperfusion therapy are being initiated. Patients should be questioned about recent use of a phosphodiesterase inhibitor (PDE) because administration of nitroglycerin within 24 hours of a PDE may cause life-threatening hypotension. A meta-analysis performed before the age of routine reperfusion suggested a mortality benefit with intravenous nitroglycerin (8), although routine use of oral nitrates after MI had no benefit in two large randomized trials in the modern era. Nitroglycerin can be useful in the management of acute MI complicated by CHF, ongoing symptoms, or hypertension. A 30% reduction in systolic blood pressure can be expected with appropriately

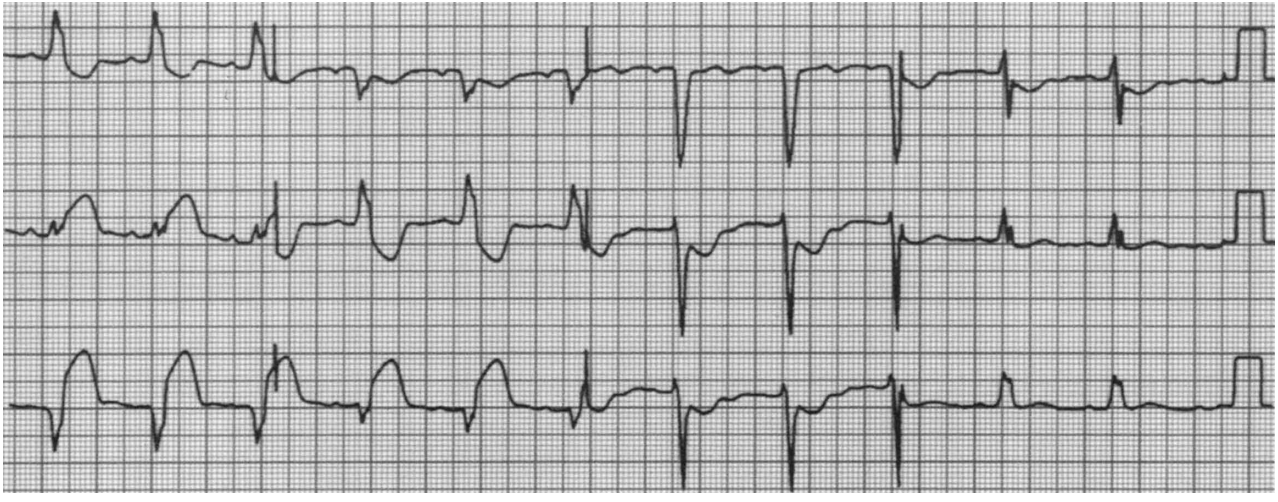

FIGURE 1.3 Electrocardiogram displays all of the criteria for the diagnosis of acute myocardial infarction (MI) in the setting of left bundle branch block (LBBB): ST-segment elevation > 1 mm, concordant with QRS in lead II (5 points); ST-segment depression > 1 mm in leads V_2 and V_3 (3 points); and ST-segment elevation > 5 mm, discordant with QRS in leads III and VF (2 points). A score of 10 points indicates an extremely high likelihood of inferior MI. (From Sgarbossa EB, Wagner G, 1997, with permission.)

TABLE 1.5 30-Day Mortality Based on Hemodynamic (Killip) Class

Killip class	Characteristics	Patients (%)	Mortality rate (%)
I	No evidence of CHF	85	5.1
II	Rales, ↑ JVD, or S_3	13	13.6
III	Pulmonary edema	1	32.2
IV	Cardiogenic shock	1	57.8

CHF, congestive heart failure; ↑, increased; JVD, jugular venous distention; S_3, third heart sound.

Adapted from Lee KL, Woodlief LH, Topol EJ, et al. Predictors of 30-day mortality in the era of reperfusion for acute myocardial infarction. Results from an international trial of 41,021 patients. GUSTO-I Investigators. *Circulation.* 1995;91:1659-1668.

TABLE 1.6 TIMI Risk Model for Prediction of Short-Term Mortality in ST-Segment Elevation Myocardial Infarction Patients

History	
Age 65–74 years	2 points
Age ≥ 75 years	3 points
Angina or DM/HTN	1 point
Physical examination	
HR > 100 bpm	2 points
SBP < 100 mm Hg	3 points
Killip class II–IV	2 points
Weight < 67 kg	1 point
Presentation	
Anterior ST elevation or LBBB	1 point
Time to treatment > 4 h	1 point
TIMI risk score = total points (0–14)	

DM, diabetes mellitus; HR, heart rate; HTN, hypertension; LBBB, left bundle branch block; SBP, systolic blood pressure; TIMI, thrombolysis in myocardial infarction.

Adapted from Morrow DA, Antman EM, Charlesworth A, et al. TIMI risk score for ST-elevation myocardial infarction: a convenient, bedside, clinical score for risk assessment at presentation: an intravenous nPA for treatment of infarcting myocardium early II trial substudy. *Circulation.* 2000;102:2031-2037.

aggressive dosing (10 to 20 μg/min with 5 to 10 μg/min increases every 5 to 10 minutes). Intravenous therapy can be continued for 24 to 48 hours, after which time patients with heart failure or residual ischemia can transition to oral or topical therapy with an appropriate nitrate-free interval to avoid tachyphylaxis.

4. **Platelet $P2Y_{12}$ receptor antagonists** should be used routinely in all patients with STEMI regardless of whether or not PCI is performed (9). Currently, the three agents recommended for treatment of STEMI are clopidogrel, prasugrel, and ticagrelor. Clopidogrel and prasugrel are thienopyridines that irreversibly inhibit the platelet adenosine diphosphate $P2Y_{12}$ receptor, and Ticagrelor is a reversible direct inhibitor of this same receptor. In patients in whom PCI is planned, a loading dose should be given prior to or at the time of PCI. The recommended loading dose of clopidogrel is 600 mg. This is largely based on results of a meta-analysis that included more than 25,000 patients undergoing PCI. The meta-analysis demonstrated that when compared to 300 mg, a 600 mg clopidogrel loading dose reduces MACE without an increase in major bleeding. (10). The recommended loading dose of prasugrel is 60 mg (9). Prasugrel is considered to be superior to clopidogrel in onset of action and potency of platelet inhibition; in addition, its metabolism is not influenced by cytochrome P450 genetic polymorphisms. The TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis In Myocardial Infarction) investigators compared efficacy and safety of prasugrel versus clopidogrel in patients with moderate- to high-risk ACS undergoing PCI. The primary end point was a composite of death due to cardiovascular causes, nonfatal MI, or nonfatal stroke. Patients who received prasugrel had a significant reduction in the primary end point compared with patients who received clopidogrel (9.9% vs. 12.1%; hazard ratio [HR] 0.81; 95% confidence interval [CI], 0.73 to 0.90; $p < 0.001$). This difference was primarily driven by a reduction in nonfatal MI (7.3% for prasugrel vs. 9.5% for clopidogrel; HR 0.76; 95% CI, 0.67 to 0.85; $p < 0.001$). The risk of TIMI major bleeding was higher with the use of prasugrel (2.4% vs. 1.8%; HR 1.32; 95% CI, 1.03 to 1.68; $p = 0.03$), though the net clinical benefit end point, which included all-cause mortality, ischemic events, and major bleeding events, still favored the use of prasugrel (11). Based on subgroup analysis, diabetics derived a greater benefit with prasugrel as compared with clopidogrel, whereas post hoc analysis showed that patients 75 years of age or older or patients with a body weight of < 60 kg derived no net clinical benefit from prasugrel. Post hoc analysis also showed net harm in patients treated with prasugrel who had a history of a transient ischemic attack or stroke, and therefore prasugrel should be avoided in these patients (11). Ticagrelor is given as a 180 mg loading dose. Platelet inhibition with ticagrelor occurs faster and is more potent than clopidogrel. The efficacy and safety of ticagrelor was compared to clopidogrel in the PLATO (Platelet Inhibition And Patient Outcomes)trial. At one year, patients who received ticagrelor had a significant reduction in the composite endpoint of death from vascular causes, MI, or stroke, without an increase in major bleeding. Of note, patients who receive ticagrelor should not be treated with high dose aspirin, which has been associated with worse outcomes in these patients (12). Currently, guidelines do not endorse one agent over another except in patients who have received fibrinolysis. In these patients, clopidogrel is the thienopyridine of choice, at a loading dose of 300 mg if fibrinolysis was performed within 24 hours of administration (13). This is based on results of the CLARITY-TIMI 28 (Clopidogrel as Adjunctive Reperfusion Therapy—Thrombolysis in Myocardial Infarction) trial, which showed pretreatment with clopidogrel to be safe and effective without increased bleeding among patients treated with fibrinolytic therapy, with many receiving subsequent PCI (-57%). The composite end point of cardiovascular death, reinfarction or revascularization, was reduced from 14.1% to 11.6% ($p = 0.03$) by clopidogrel pretreatment (9,13). In patients receiving a stent (BMS or drug-eluting stent [DES]), thienopyridine therapy should be continued for at least 1 year (9).

The maintenance dose of clopidogrel and prasugrel is 75 mg daily and 10 mg daily, respectively. The maintenance dose for prasugrel is 90 mg twice a day. An important consideration is the increased risk of major bleeding during surgery. It is currently recommended that clopidogrel and ticagrelor be held for 5 days and prasugrel be held for 7 days prior to CABG, unless the need for urgent revascularization outweighs the risk of potential excessive bleeding (9).

5. **Parenteral anticoagulants.** Unless there is a contraindication, all STEMI patients should receive antithrombotic therapy. Traditionally, this has been accomplished with unfractionated heparin (UFH). The dose of UFH is 60 U/kg as a bolus (maximum 4,000 U), followed by 12 U/kg/h infusion (maximum 1,000 U/h) to achieve a partial thromboplastin time of 45 to 65 seconds (7). Based on the GUSTO I (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) trial, heparin should be given as an adjunct to patients who receive thrombolysis with alteplase, but should not be given to patients who receive streptokinase unless the patient has recurrent ischemia or there is another indication for anticoagulant therapy (14). The use of UFH as adjunctive therapy with reteplase and tenecteplase (TNK) has been validated in GUSTO III and ASSENT 2 (Assessment of the Safety and Efficacy of a New Thrombolytic), respectively. Low-molecular-weight heparin (LMWH) is an alternative to UFH and should be preferred in patients undergoing fibrinolysis. The ASSENT 3 trial tested the efficacy of various antithrombotic regimens in conjunction with weight-based TNK. TNK plus enoxaparin was superior to TNK plus UFH in reducing the composite end point of death, in-hospital reinfarction, or in-hospital refractory ischemia (15). Similarly, the ExTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment - Thrombolysis in Myocardial Infarction) trial randomized STEMI patients undergoing fibrinolysis to either enoxaparin throughout the index hospitalization or UFH for 48 hours. The primary end point was death or nonfatal MI at 30 days. The enoxaparin group had a significant reduction in the primary end point, most of which was due to a significant reduction in the rate of reinfarction (3.0% vs. 4.5%). The enoxaparin group was also less likely to undergo urgent revascularization (2.1% vs. 2.8%). It is worth noting that duration of therapy differed between the two groups. Although UFH was only administered for 48 hours, LMWH therapy was continued for a mean of 7 days (16). Patients undergoing PCI after treatment with LMWH may need additional dosing in the cardiac catheterization laboratory, depending on the time at which the last dose was administered. If the last dose was within 8 hours, no additional enoxaparin should be given. If the last dose was given 8 to 12 hours earlier, an intravenous dose of 0.3 mg/kg should be given. If it has been > 12 hours since that last dose, an additional 1 mg/kg dose should be administered subcutaneously. LMWH should be avoided in patients > 75 years old or in patients with significant renal insufficiency (22). The 2009 focused update of the ACC/AHA STEMI guidelines added bivalirudin as an acceptable anticoagulant in patients undergoing primary PCI (9). The 2011 ACCF/AHA/SCAI PCI guideline confirmed this with a class I recommendation for bivalirudin during PCI (17). This is primarily based on results of the HORIZONS-AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial. The HORIZONS-AMI trial randomized 3,600 patients to either bivalirudin and provisional glycoprotein (GP) IIb/IIIa inhibitor or UFH and planned GP IIb/IIIa inhibitor prior to primary PCI. The primary end point was the 30-day rate of the combined outcome of net adverse clinical events, including major bleeding, death, reinfarction, target vessel revascularization (TVR), and stroke. Patients in the bivalirudin group

had a significant reduction in the primary end point (9.2% vs. 12.1%; relative risk [RR] 0.76; 95% CI, 0.63 to 0.92; $p = 0.005$) primarily due to decreased major bleeding (4.9% vs. 8.3%; $p = 0.001$). The benefit was maintained at 1 year (18). Fondaparinux is a synthetic pentasaccharide factor Xa inhibitor that has also been studied in acute MI. The OASIS-6 (Organization for the Assessment of Strategies for Ischemic Syndromes) trial evaluated fondaparinux with fibrinolytics and appeared to demonstrate benefit versus placebo/UFH in terms of death and reinfarction at 30 days (9.7% vs. 11.2%; HR – 0.86; 95% CI, 0.77 to 0.98; p = 0.008) without an increased risk of bleeding (19). However, in the primary PCI subset, there was no benefit and a significant increase in guiding catheter thrombosis, which has limited its widespread use. Accordingly, current ACC/AHA guidelines recommend that patients treated with fondaparinux receive additional anticoagulation with an anti-IIa agent prior to proceeding with PCI.

B. Reperfusion therapy. The primary goal in the management of acute MI is to institute reperfusion therapy as quickly as possible. All patients with ST-segment elevation or new LBBB MI who seek treatment within 12 to 24 hours from onset of continuous symptoms should be considered for immediate reperfusion therapy. Persistent ischemic symptoms after 12 hours may indicate a stuttering course of occlusion, spontaneous reperfusion, and reocclusion and may indicate potential continued benefit for early therapy.

1. **Benefit.** The benefit of reperfusion therapy has been well documented in the management of acute MI, regardless of age, gender, and most baseline characteristics. However, the patients who derive the most benefit are those treated earliest and those at highest risk, such as those with anterior MI.
2. **Time to treatment is paramount.** Patients treated in the first hour have the highest mortality benefit. **There is an inverse relationship between time to treatment and survival benefit**. This relationship appears more consistent with fibrinolytic therapy than with direct PCI. After 12 hours of continuous symptoms, there is little net benefit to pharmacologic reperfusion with fibrinolytics. The therapeutic window for PCI extends beyond that of fibrinolysis, but is not infinite (20,21). The Occluded Artery Trial (OAT) suggests that stenting of an occluded infarct-related artery > 72 hours after the initial event is not associated with benefit and may be harmful (21). Currently, the AHA recommends against PCI of an occluded infarct-related artery > 24 hours after STEMI if the patient is hemodynamically stable and does not have signs of severe ischemia (22).
3. **Fibrinolysis versus direct PCI.** After it has been determined that a patient is a candidate for reperfusion therapy, the decision to use fibrinolytic or direct PCI therapy must be made quickly.
   a. If facilities for immediate coronary angiography and PCI are available within 90 minutes of first medical contact, this is the preferred therapy. Pooled data from several large trials show a significant (22%) reduction in short-term mortality for patients treated with primary angioplasty (23). This benefit was durable because there were significant reductions in the incidence of death, nonfatal MI, and recurrent ischemia at long-term follow-up. PCI is also associated with a reduction in the incidence of intracerebral hemorrhage compared with fibrinolytic therapy.
   b. If facilities for immediate coronary angiography and direct PCI are not available, fibrinolytic therapy, unless contraindicated, should be instituted within 30 minutes of first medical contact. There is some controversy regarding the use of primary PCI with prolonged transfer times. Several trials, including the DANAMI-2 (Danish Multicenter Randomized Study on Thrombolytic Therapy Versus Acute Coronary Angioplasty in Acute Myocardial Infarction) (24), the Air-PAMI (Air-Primary Angioplasty in

Myocardial Infarction) (25), and the PRAGUE (Primary Angioplasty in Patients Transferred from a General Community Hospital to Specialized PTCA Units) (26), have investigated the benefit of on-site fibrinolysis compared with transfer to tertiary centers for direct PCI. These studies have found improved outcomes in patients randomized to a transfer strategy and direct PCI even after taking into account the increased time for patient transfer. For example, patients in DANAMI-2 randomized to transfer for PCI had a significantly lower 30-day incidence of death, MI, or stroke (8.5% vs. 14.3%; $p = 0.002$) despite a median time from randomization to balloon inflation of 112 minutes. According to current guidelines, if a patient presents with STEMI at a PCI-capable facility and can undergo PCI within 90 minutes of first medical contact, this is the preferred approach. Conversely, if the patient presents to a hospital without PCI capability and cannot receive PCI within 120 minutes of first medical contact, fibrinolytics should be administered within 30 minutes of hospital presentation (17,22). This assumes that there are no contraindications to fibrinolysis (Table 1.7).

c. If a contraindication to fibrinolytic therapy exists or there is some question of the diagnosis, arrangements should be made for transfer to a PCI facility.

TABLE 1.7 Contraindications and Cautions for Use of Thrombolytic Agents to Manage Myocardial Infarction

Absolute contraindications
Previous hemorrhagic stroke at any time; ischemic stroke within 3 mo
Known intracranial neoplasm, structural cerebral vascular lesion, or closed head injury within 3 mo
Active bleeding or bleeding diathesis (excluding menses)
Suspected aortic dissection
Relative contraindications
Severe, uncontrolled hypertension at presentation (blood pressure > 180/110 mm Hg) or history of chronic severe hypertension
History of ischemic stroke > 3 mo, dementia, or known intracerebral pathologic condition not covered in contraindications
Current use of anticoagulants, the risk increases with increasing INR
Traumatic or prolonged (> 10 min) CPR or major surgery (< 3 wk)
Noncompressible vascular punctures
Recent (within 2–4 wk) internal bleeding
For streptokinase or anistreplase: prior exposure (> 5 d prior) or prior allergic reaction
Pregnancy
Active peptic ulcer

CPR, cardiopulmonary resuscitation; INR, international normalized ratio.

Adapted from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction). *J Am Coll Cardiol.* 2004;44:E1–E211.

d. Because of the relative lack of efficacy of lytic therapy among patients with cardiogenic shock or prior bypass operations, such patients are especially well suited for primary PCI.

4. Primary PCI. Once the decision has been made to perform reperfusion with primary PCI, the patient should be moved to the cardiac catheterization laboratory and undergo angiography as rapidly as possible. After the culprit lesion has been identified, reperfusion should be achieved with standard PCI techniques (see Chapter 65).

a. Platelet GP IIb/IIIa inhibitors. Several clinical trials, including RAPPORT (ReoPro and Primary PTCA Organization and Randomized Trial) and ADMIRAL (Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-Term Follow-up), have documented the benefits of abciximab in improving clinical outcomes after primary PCI with or without stenting in patients with STEMI (27,28). Despite these trials, the emergence of potent platelet ADP $P2Y_{12}$ receptor inhibtors has sparked controversy regarding the benefit of GP IIb/IIIa treatment in STEMI patients receiving dual, oral antiplatelet therapy. Three major trials have evaluated the efficacy of GP IIb/IIIa therapy in STEMI patients receiving dual, oral antiplatelet therapy. The Bavarian Reperfusion AlternatiVes Evaluation-3 (BRAVE-3) study looked at 800 STEMI patients who received aspirin plus 600 mg of clopidogrel and either abciximab or placebo during PCI. The primary end point was infarct size measured by single photon emission computed tomography prior to hospital discharge. The study also compared 30-day major adverse cardiovascular events (MACE) between the two groups. Compared with placebo, abciximab offered no additional benefit in terms of reducing infarct size or MACE (28,29). On-TIME 2 was a randomized control trial in Europe that compared outcomes in STEMI patients undergoing PCI who were treated with aspirin and 600 mg of clopidogrel plus either high-dose tirofiban or placebo. Patients in the high-dose tirofiban group had improved ST-segment resolution at 1 hour, but there was no significant difference in TIMI grade 3 flow or 30-day MACE (30). Lastly, in the HORIZONS-AMI trial, patients undergoing primary PCI for STEMI were randomized to either UFH plus a GP IIb/IIIa or bivalirudin with provisional GP IIb/IIIa therapy. All patients received aspirin and thienopyridine therapy prior to PCI. At 30 days, net adverse clinical events were higher in patients treated with a GP IIb/IIIa, primarily due to increased bleeding (18).

The timing of GP IIb/IIIa therapy has also been questioned. The FINESSE (Facilitated Intervention with Enhanced Speed to Stop Events) trial compared half-dose reteplase with abciximab, abciximab alone, or placebo (primary PCI) in patients undergoing PCI for STEMI. Although more patients with fibrinolytic plus GP IIb/IIIa therapy had an open artery on arrival to the catheterization laboratory, the composite primary end point of death or complications of MI at 90 days was no different among the various strategies (9.8% half-dose fibrinolytic + GP IIb/IIIa inhibitor, 10.5% GP IIb/IIIa inhibitor alone, and 10.7% placebo; p = NS), suggesting no benefit to upstream GP IIb/IIIa therapy (31). In addition, bleeding rates were higher with half-dose fibrinolytic + GP IIb/IIIa inhibitor (31).

Meta-analyses have been performed to compare the efficacy of small molecule GP IIb/IIIa inhibitors with abciximab in STEMI patients undergoing PCI. Results show no statistically significant difference in 30-day mortality, reinfarction, major bleeding, TIMI grade 3 flow, or ST-segment resolution between eptifibatide, tirofiban, and abciximab (32,33).

Based on all available data, if a patient has no contraindication to dual, oral antiplatelet therapy, it is reasonable to reserve the use of GP IIb/IIIa

therapy until coronary anatomy has been defined. Current ACC/AHA guidelines reflect this practice, as GP IIb/IIIa administration during PCI carries a class IIa recommendation, while upstream use is classified as class III (17). Also according to current guidelines, abciximab, tirofiban, and eptifibatide are considered equivalent options for GP IIb/IIIa therapy in patients undergoing PCI for STEMI (9).

b. **Thrombus aspiration.** The use of aspiration catheters has been shown to improve ST-segment resolution and myocardial blush and more recently has been associated with improved clinical outcomes. TAPAS (Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction Study) was a single-center, randomized, clinical trial that compared manual thrombus aspiration before PCI with conventional balloon angioplasty and stenting in patients with STEMI (34). Unless contraindicated, all patients were treated with aspirin, 600 mg of clopidogrel, UFH, and abciximab. Complete resolution of ST-segment elevation occurred in significantly more patients who received aspiration thrombectomy when compared with patients who underwent conventional balloon angioplasty and PCI (56.6% vs. 44.2%; $p < 0.001$). In addition, a TIMI myocardial blush grade of 0 or 1 occurred in 17.1% of patients who received aspiration thrombectomy compared with 26.3% of patients who received conventional PCI ($p < 0.001$) (34). Although death, reinfarction, and TVR rates did not differ at 30 days, at 1 year there was a significant reduction in the rates of cardiac death (3.6% vs. 6.7%; $p = 0.02$) and cardiac death or nonfatal reinfarction (5.6% vs. 9.9%; $p = 0.009$) in the thrombus aspiration group (34,35). Based on current guidelines, thrombus aspiration is considered reasonable during PCI in patients with STEMI who have a high clot burden and short ischemic times (9).

c. **Distal embolic protection devices (EPDs)** have failed to show any benefit in multiple trials and may in fact increase infarct size. The major criticism of these trials is the exclusion of patients with large thrombus burden. Regardless of this caveat, these devices are not routinely recommended for acute PCI of native coronary arteries. If the culprit vessel is a saphenous vein bypass graft, an EPD should be used, as it has been shown to reduce a 30-day composite outcome of death, MI, emergency CABG, and target-lesion revascularization (TLR).

d. **Coronary stenting.** The early benefit of angioplasty over thrombolytic therapy is attenuated with more extended follow-up. In the GUSTO IIb expanded previously trial in which use of accelerated tissue plasminogen activator (tPA) was compared with angioplasty alone (percutaneous transluminal coronary angioplasty, PTCA), the reduction in rates of death and nonfatal MI at 30 days (13.7% tPA vs. 9.6% PTCA) dwindled, and by 6 months, the difference (16.1% for tPA vs. 14.1% for PTCA) had lost statistical significance (36). This loss of effect may be at least partially caused by restenosis of the target lesion that was managed directly with angioplasty. Although coronary stents are known to reduce rates of restenosis during elective PCI, it was once believed that stents should not be placed in thrombus-laden lesions, such as those associated with acute MI, because of risk of in-stent thrombosis. However, clinical trials with adequate antiplatelet therapy have shown stenting to be safe. The STENT-PAMI (STENT-Primary Angioplasty in Myocardial Infarction) (37) study found that coronary stenting significantly reduced the need for TVR at 6 months (7.7% vs. 17.0%; $p < 0.001$). These findings were confirmed in the CADILLAC (Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications) (38) trial, which found that coronary stenting significantly reduced the incidence of restenosis at 6 months (40.8% vs. 22.2%; $p < 0.0001$),

independent of abciximab use. Based on several meta-analyses, there does not appear to be a difference between DES and BMS in terms of mortality, MI, or risk of stent thrombosis (39–41). There is, however, a reduction in TVR with DES (39–41). This was also seen in the HORIZONS-AMI trial, which randomized > 3,000 patients to DES or BMS in a 3:1 ratio. At 12 months, there was no difference in the composite end point of death, reinfarction, stroke, or stent thrombosis; however, DES patients had a decreased rate of ischemia-driven TVR and TLR (5.8% vs. 8.7% and 4.5% vs. 7.5%, respectively) (18,42). Accordingly, patients with the highest risk of in-stent restenosis such as diabetics and patients with long, smaller diameter coronary lesions derive the greatest benefit from DES. In 2009, the ACC/AHA guidelines were updated to include DES as an alternative to BMS in patients undergoing primary PCI for STEMI (9). As mentioned by the ACC/AHA writing group members, the greatest challenge in determining if a STEMI patient is a candidate for DES is deciding in an emergent situation if the patient is a candidate for prolonged dual-antiplatelet therapy. The ideal candidate for a DES should not have social or financial barriers to prolonged dual-antiplatelet therapy, should have no surgical procedures scheduled within the next year, and should be at low risk for bleeding complications (9).

5. **Fibrinolytic therapy.** The lifesaving capability of early fibrinolytic therapy has been well established, beginning with the GISSI 1 (Gruppo Italiano per lo Studio della Sopravivenza nell'Infarto Miocardico) trial (43) in 1986. Pooled data show a relative reduction in mortality of 18% and an absolute reduction of nearly 2%. Even more dramatic long-term mortality benefit may be the result of preservation of normal LV function.
   a. **Contraindications.** As discussed previously (Table 1.7), the only **absolute contraindications to fibrinolytic therapies are recent cerebrovascular accident (CVA), hemorrhagic CVA, intracranial neoplasm, active internal bleeding, and suspected aortic dissection**. The presence of one of these or one or more of the relative contraindications would favor PCI, even if it meant delaying reperfusion.
   b. **Choice of agent**
      (1) **Alteplase (tPA).** The GUSTO I previously expanded trial showed that use of accelerated alteplase significantly reduced 30-day mortality rate by 15% relative to SK plus subcutaneous or intravenous heparin (14). This mortality reduction correlated with significantly higher rates of TIMI 3 flow at 90 minutes compared with SK (54% vs. 31%; $p < 0.001$). The benefit was initially challenged because of the high cost of alteplase (approximately US $2,200 per episode of MI) compared with SK (approximately US $300). For alteplase, this corresponds to a cost of US $32,678 per year of life saved, less than that of the well-accepted standard of hemodialysis for end-stage renal disease (44). The benefit was seen across all subgroups, although the patients at highest risk derived the most benefit. The accelerated protocol consisted of an intravenous bolus dose of 15 mg followed by 0.75 mg/kg (up to 50 mg) over 30 minutes and then 0.5 mg/kg over 60 minutes. Alteplase is considered a fibrin-specific agent because of its relative selectivity for clot-bound fibrin.
      (2) **Reteplase.** The first of the third-generation fibrinolytic agents approved for use in the United States, reteplase, is a less fibrin-specific mutation of alteplase. Reteplase has a longer half-life than alteplase and can be administered in a double bolus (10 mg each, 30 minutes apart). The GUSTO III trial (45) showed no mortality benefit of reteplase over alteplase, but its ease of use may help to reduce time to administration.

(3) **Tenecteplase**, another third-generation fibrinolytic, is characterized by its improved fibrin specificity, enhanced resistance to plasminogen activator inhibitor 1, and decreased plasma clearance. These properties allow it to be administered as a single bolus. The ASSENT 2 trial found no mortality difference between TNK and tPA at 30 days (46). However, TNK was associated with significantly less noncerebral bleeding and improved mortality in patients treated for > 4 hours after symptom onset. The weight-adjusted dose of TNK is 30 to 40 mg (ASSENT 1).

(4) **Streptokinase.** This first-generation nonfibrin-specific lytic is a reasonable alternative to second- or third-generation agents if newer agents are not available or cannot be used because of limited financial resources. Because of the possible development of antibodies, SK should not be administered to a patient who has received it in the past. Because the overall rate of intracerebral hemorrhage is lower with SK (0.5%) than with tPA (0.7%), some cardiologists advocate its use in the care of high-risk patients, such as elderly patients with a history of a cerebrovascular event or severe hypertension. SK is a nonfibrin-specific agent capable of lysing circulating and clot-bound plasminogen to plasmin. This process results in substantial systemic fibrinogenolysis, fibrinogenemia, and elevation in fibrin degradation products.

c. **Bleeding complications after fibrinolysis.** The most serious **complication** of fibrinolytic therapy is **intracerebral hemorrhage, which occurs in approximately 0.5% to 0.7% of patients receiving such therapy. The major risk factors for intracranial hemorrhage include age (> 75 years), hypertension, low body weight, female gender, and coagulopathy** (e.g., prior Coumadin use). The diagnosis must be considered if a patient has severe headache, visual disturbances, new neurologic deficit, acute confusional state, or seizure. If the clinical suspicion is high, fibrinolytic, antithrombin, and antiplatelet therapy should be interrupted while emergency CT or MRI is performed and neurosurgical consultation is obtained. Surgical evacuation may be lifesaving. Even with prompt recognition and treatment, the mortality rate is higher than 60%; elderly patients (> 75 years) have a mortality rate higher than 90%. There is controversy regarding the risk of fibrinolytic therapy in elderly patients. An observational study (47) from the Medicare database found that patients older than 75 years had an increased risk of death at 30 days with fibrinolytic therapy (RR = 1.38; 95% CI, 1.12 to 1.71; $p = 0.003$). However, an updated meta-analysis of nine randomized trials (48,49) found that the risk reduction with fibrinolysis in patients older than 75 years was 16% (odds ratio = 0.84; 95% CI, 0.72 to 0.98; $p < 0.05$). There appears to be a decreasing relative benefit with fibrinolysis in the elderly, but an absolute gain in lives saved. The only randomized trial to specifically study management of STEMI in the elderly found that patients treated with PCI had significantly lower 30-day and 1-year mortality rates than patients treated with fibrinolysis (49). However, the ExTRACT-TIMI 25 study more recently indicates that fibrinolytic therapy may be safe in the elderly if a reduced dose of enoxaparin is used (16). Gastrointestinal, retroperitoneal, and access site bleeding may complicate fibrinolytic therapy but are usually not life-threatening if promptly recognized and managed. In any case, the best treatment of acute STEMI in elderly patients appears to be primary PCI.

d. **Prehospital fibrinolysis.** Early administration of fibrinolytic therapy by emergency services has been shown to potentially reduce infarct size but lacks solid randomized trial data advocating its routine use. It has also been found to reduce time to treatment (50,51), but this did not translate

into a reduction in mortality. Although a meta-analysis (52) of prehospital fibrinolytic trials did find a 17% reduction of in-hospital mortality, it remains to be seen whether this strategy can improve long-term outcomes in clinical practice.

6. **Combination fibrinolytic therapy with GP IIb/IIIa inhibitors (without PCI)**
   a. **Rationale.** Sustained tissue-level reperfusion occurs in only 25% of patients treated with fibrinolytic therapy. Platelets have paradoxically increased activity after fibrinolysis and are important mediators in the tendency for vessel reocclusion. Aspirin is pathway specific and, therefore, a relatively weak antiplatelet agent. GP IIb/IIIa inhibitors, however, are potent antiplatelet agents that block the final common pathway of platelet aggregation, and for this reason, they have been studied in combination with half-dose fibrinolysis.
   b. **Clinical trials.** GUSTO V found that the addition of abciximab to half-dose reteplase did not reduce mortality at 30 days or 1 year compared with full-dose reteplase, but it did reduce reinfarctions and complications after MI (53). ASSENT 3 also found comparable reductions in reinfarction with the combination of half-dose TNK and abciximab (15).
   c. **Contraindications.** GUSTO V found that the rate of intracranial hemorrhage in elderly patients (> 75 years) treated with combination therapy was almost twice that of standard lytic therapy (2.1% vs. 1.1%; $p = 0.07$). ASSENT 3 confirmed this finding. Age older than 75 years is, therefore, an additional contraindication for combination lytic therapy. No increase in intracranial hemorrhage was seen in younger patients.
7. **Rescue percutaneous revascularization** is defined as the use of PCI when fibrinolytic therapy has proved unsuccessful. Despite the proven mortality benefit, > 30% of patients who received lytic therapy have TIMI 0 to 1 flow at 90 minutes, whereas patency at 90 minutes has been shown to correlate with long-term survival (54). If reperfusion is not clearly evident 90 minutes after initiation of lytic therapy, particularly among patients with large acute MI, the decision to perform emergency angiography and mechanical reperfusion should be made promptly. Patients in cardiogenic shock, with severe CHF, or with compromising arrhythmias after lytic therapy should undergo immediate coronary angiography and should not await clinical assessment of reperfusion.
   a. **Clinical determination of successful reperfusion.** It can be difficult to determine clinically whether a patient has successful reperfusion with fibrinolytic therapy. Resolution of chest pain is an inaccurate measure of reperfusion, because the pain may be blunted by narcotic analgesia or the partial denervation that is known to occur among some patients with MI. Serial assessment of 12-lead ECGs is a more reliable indicator of reperfusion, although it is also suboptimal. An accelerated idioventricular rhythm (AIVR) is fairly specific for reperfusion, but arrhythmias other than AIVRs are not reliable indicators because a variety of ventricular and supraventricular arrhythmias may be observed in patients with nonreperfused infarction-related artery. The complete resolution of chest pain and electrocardiographic changes (defined as > 70% resolution of ST-segment elevation), accompanied by a run of AIVR, is highly specific for successful reperfusion, but it occurs in < 10% of patients receiving lytic therapy. Resolution of ST-segment elevation by > 70% is correlated with effective tissue-level reperfusion, and this finding has been correlated with better clinical outcomes and angiographic reperfusion.
   b. **Benefit.** It has been shown in the RESCUE (Randomized Evaluation of Salvage Angioplasty with Combined Utilization of Endpoints) trial (55) that patients with anterior MI who have unsuccessful thrombolysis (TIMI 0 or

1 flow) have a significant benefit from rescue angioplasty. In addition, the Rapid Early Action for Coronary Treatment (REACT) trial demonstrated that among patients with failed reperfusion with lytics, treatment with rescue angioplasty with or without PCI is associated with an ~50% reduction in death, reinfarction, stroke, and severe heart failure (56). The Grupo de Análisis de la Cardiopatía Isquémica Aguda I (GRACIA I) trial evaluated an early invasive strategy (within 24 hours) versus an ischemia-guided approach among patients with STEMI treated with fibrinolytic therapy. This trial primarily demonstrated a reduction in revascularization events with the early invasive approach, although a trend was seen toward fewer deaths and reinfarcts. Based on the above data, an early angiography strategy (within 24 hours) may also be considered a reasonable approach in all patients who receive lytic therapy. However, this approach should be differentiated from the facilitated PCI strategy described later.

8. **Facilitated PCI** refers to the use of an initial pharmacologic regimen to improve vessel patency rates prior to planned PCI. This method has been proposed as a way to manage patients with acute MI who present to hospitals without 24-hour catheterization laboratory facilities. Various facilitated PCI strategies have been proposed, including high-dose heparin, early GP IIb/IIIa inhibitors, full-dose or reduced-dose fibrinolytics, and combination fibrinolytics and GP IIb/IIIa inhibitors. Theoretical advantages include earlier time to reperfusion, improved hemodynamic stability, smaller infarct size, greater procedural success, and improved survival, albeit at increased risk for bleeding complications. The ASSENT 4 PCI previously expanded trial was the largest study to evaluate full-dose fibrinolytic therapy (TNK) plus PCI versus primary PCI alone. The trial was terminated prematurely because of higher in-hospital mortality rates (6% vs. 3%; $p = 0.01$) and higher primary composite end points (death, shock, and heart failure within 90 days) with full-dose fibrinolytics plus PCI versus primary PCI alone (18.6% vs. 13.4%; $p = 0.0045$) (57). As discussed previously, the FINESSE trial randomized STEMI patients undergoing PCI to half-dose reteplase with abciximab, abciximab alone, or placebo (primary PCI). Although more patients with fibrinolytic plus GP IIb/IIIa inhibitor had an open artery on arrival to the catheterization laboratory, the composite primary end point of death or complications of MI at 90 days was no different among the various strategies (9.8% half-dose fibrinolytic + GP IIb/IIIa inhibitor, 10.5% GP IIb/IIIa inhibitor alone, and 10.7% placebo; p = NS), the bleeding rates being higher with the half-dose fibrinolytic plus GP IIb/IIIa inhibitor. Finally, a large meta-analysis of multiple smaller trials confirmed that primary PCI is superior to facilitated PCI (58).
9. **Pharmacoinvasive Strategy.** Though it is clear that routine fibrinolysis prior to transfer for PCI in all patients who present with AMI (facilitated PCI) results in worse outcomes, fibrinolysis is still necessary to achieve early reperfusion in some patients who present to non-PCI-capable facilities. More recent data suggest that high risk patients (Table 1.8) who receive fibrinolytic therapy benefit from immediate transfer for PCI. The CARESS-in-AMI (Combined Abciximab REteplase Stent Study in Acute Myocardial Infarction) trial (59) randomized patients presenting to a non-PCI-capable facility, who received half-dose fibrinolytics and abciximab, to either immediate transfer for PCI or rescue PCI. Patients who were transferred immediately for PCI had a significant reduction in the primary endpoint of death, reinfarction, or refractory ischemia at 30 days (59). In addition, the TRANSFER-AMI (Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction) study showed that high-risk patients benefit from this pharmacoinvasive strategy. This trial looked at 1,059 high-risk patients with STEMI who presented to a non–PCI-capable facility within 12 hours of symptom onset (60). All patients

received fibrinolysis with TNK and were then randomized to immediate transfer for PCI or rescue PCI dictated by continued chest pain, < 50% resolution of ST elevation, or hemodynamic instability. The primary end point was 30-day composite of the first occurrence of death, MI, recurrent ischemia, new or worsening heart failure, and cardiogenic shock. The primary end point was significantly less common in the pharmacoinvasive group compared with the group who received rescue PCI (11% vs. 17.2%; RR 0.64; 95% CI, 0.47 to 0.87; $p = 0.004$) (60). Based on the CARESS-in-AMI and TRANSFER-AMI trials, the ACC/AHA now recommends abandoning the use of the terms "facilitated" and "rescue" and rather decide on transfer for PCI based on the patient's level of risk (9). High-risk patients (Table 1.8) who receive fibrinolysis as the primary reperfusion strategy should be transferred to a PCI-capable facility as soon as possible. PCI can then be performed immediately or as needed. For low-risk patients, this management strategy is a class IIb recommendation (9).

10. **The late open artery hypothesis** postulates that benefit in terms of improved ventricular function, increased electrical stability, and provision of collaterals can be gained by late patency of occluded infarct arteries. However, OAT failed to show benefit of angioplasty for late total occlusion within 3 to 28 days after MI (21). Criticism of this trial includes exclusion of high-risk patients with New

TABLE 1.8 ACC/AHA Definition of High-Risk Patients with Acute Myocardial Infarction

Defined in CARESS-in-AMI

(1) STEMI patients with one or more of the following:
- – Extensive ST-segment elevation
- – Previous MI
- – New-onset LBBB
- – Killip class > II or EF ≤ 35% for inferior MI

(2) Anterior MI with ≥ 2 mm or more ST elevation in two or more leads

Defined in TRANSFER-AMI

(1) ≥ 2 mm ST elevation in two anterior leads or ST elevation ≥ 1 mm in inferior leads with at least
- – SBP < 100 mm Hg
- – HR > 100 bpm
- – Killip class II–III
- – ≥ 2 mm ST-segment depression in anterior leads
- – ≥ 1 mm of ST elevation in right-sided lead V_4 indicative of RV infarct

EF, ejection fraction; HR, heart rate; LBBB, left bundle branch block; MI, myocardial infarction; RV, right ventricular; SBP, systolic blood pressure; STEMI, ST-segment elevation myocardial infarction; UFH, unfractionated heparin.

Adapted from Kushner FG, Hand M, King SB, et al. 2009 focused updates: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction (updating the 2004 guideline and 2007 focused update) and ACC/AHA/SCAI guidelines on percutaneous coronary intervention (updating the 2005 guideline and 2007 focused update). *J Am Coll Cardiol.* 2009;54:2205–2241.

York Heart Association (NYHA) class III or IV heart failure, rest angina, clinical instability, multivessel disease (left main or three-vessel disease), or severe inducible ischemia on stress testing. Regardless of these concerns, this study has led to a new **class III recommendation against PCI of a totally occluded artery > 24 hours after STEMI in asymptomatic patients without the previously noted high-risk criteria** (22).

11. **Emergency coronary bypass surgery** may be the treatment of choice for patients in whom the intent is to perform direct or rescue percutaneous mechanical reperfusion but who are found to have a critical left main stem lesion or severe three-vessel disease unapproachable with percutaneous revascularization. Studies of this strategy are fairly encouraging, especially when patients can be taken to the operating room early in the course of infarction, before severe myocardial necrosis has occurred. RV infarction is a relative contraindication to bypass surgery because it complicates the discontinuation of cardiopulmonary support.
12. **PCI in hospitals without surgical backup.** The C-PORT (Atlantic Cardiovascular Patient Outcomes Research Team) trial (61) found a reduced 6-month composite outcome of death, MI, and stroke in patients with acute MI randomized to primary PCI versus fibrinolytic therapy (12.4% vs. 19.9%; $p = 0.03$), even when PCI was performed in hospitals without surgical backup. All the community hospitals involved in this study underwent a formal "PCI development program." Based on current PCI guidelines, it is reasonable to perform primary PCI at a facility that does not have surgical backup if there is a proven plan in place for rapid transfer to another hospital capable of performing cardiac surgery. This plan must involve the ability to use hemodynamic support if needed during transfer.

C. Adjuvant therapy

1. **β-Blockers.** Extensive data from the era before reperfusion established the usefulness of β-blockers in reducing recurrent ischemia, arrhythmias, and mortality. Several small randomized trials performed in the fibrinolytic reperfusion era confirmed the anti-ischemic and antiarrhythmic benefits, although short-term mortality was not affected. As a result, prior recommendations have stated that β-blockers should be administered to all patients within the first 24 hours of acute MI, unless contraindicated by severe reactive airway disease, hypotension, bradycardia, or cardiogenic shock. However, more recent data from the PCI era have shown no difference in mortality and no difference in the composite end point of death, reinfarction, or ventricular fibrillation arrest (62). The COMMIT/CCS-2 (Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac Study) trial, a large ($n = 22{,}929$) randomized controlled trial found that the metoprolol group had more ventricular fibrillation arrest (2.5% vs. 3.0%; $p = 0.001$) and shock (5.0% vs. 3.9%; $p < 0.001$). The incidence of shock was most notable in patients with Killip class II and III heart failure. This has led to a change in guidelines recommending more judicious use of early (< 24 hours) β-blockers, avoiding use in patients with significant signs of heart failure, low cardiac output, risk of cardiogenic shock, or other relative contraindications to their use (22).
    a. **For ongoing ischemia with tachycardia or hypertension**, after rapid evaluation of ventricular function, intravenous metoprolol can be given (5 mg every 5 minutes until the desired blood pressure and pulse are achieved). Patients who tolerate the intravenous loading can begin moderate oral doses (12.5 to 50 mg of metoprolol, two to four times daily). The dose should be subsequently titrated upward to the maximally tolerated dose (200 mg of sustained-release metoprolol, once daily). Use of β-blockers should be avoided in patients with tachycardia of unclear origin, as these

agents can decompensate heart failure in patients with compensatory tachycardia.

2. **Angiotensin-converting enzyme (ACE) inhibitors** can be started orally in the first 24 hours for all patients without hypotension, acute renal failure, or other contraindications. These medications were shown to reduce mortality in the GISSI 3 (62) and ISIS 4 (International Study of Infarct Survival) (63) trials. ACE inhibitors should be continued indefinitely in patients with LV dysfunction or clinical CHF, because these patients have been shown to derive a mortality benefit. In addition, the Heart Outcomes Prevention Evaluation (HOPE) study (64) found that high-risk patients, including those with prior MI but normal LV function, still had long-term benefit from ramipril. Intravenous formulations of these agents should not be used because they have not demonstrated benefit and may increase mortality. Rather, a graded oral regimen is advised. Angiotensin-receptor blockers remain a viable option for ACE inhibitor–intolerant patients.
3. **Calcium channel blockers.** Evidence for a potential increase in mortality has limited the use of calcium channel blockers in the care of patients with acute MI. They are indicated for the management of supraventricular tachyarrhythmia, cocaine-induced MI, or relief of postinfarction angina unresponsive to β-blockade. Otherwise, these agents should be avoided. Short-acting agents, such as nifedipine, are contraindicated because of their reflex sympathetic activation. Verapamil and diltiazem should be avoided in patients with LV dysfunction or CHF. Amlodipine is an effective antianginal agent and appears safe to use for this indication in patients with CHF.
4. **Magnesium.** There was once considerable enthusiasm for the routine use of intravenous magnesium in patients with MI, based on the findings of LIMIT 2 (Leicester Intravenous Magnesium Intervention Trial), which observed a 24% reduction in mortality compared with placebo. The larger ISIS 4 and MAGIC (Magnesium in Coronaries) trials failed to duplicate this benefit, however, and enthusiasm has waned. Some have speculated that the lack of effect in ISIS 4 was because of delayed administration or low control group mortality. In the modern era, magnesium is not routinely used other than to replete serum magnesium levels that are lower than 2.0 μg/dL or for the management of *torsade de pointes* (1 to 2 g over 5 minutes).
5. **Aldosterone antagonists.** The use of aldosterone-blocking agents has been shown to be beneficial in post-MI patients. RALES (Randomized Aldactone Evaluation Study) found a reduction in all-cause mortality with the use of aldactone in patients with ischemic cardiomyopathy and NYHA class III or IV heart failure. However, the only randomized trial to address the use of such agents among patients with ventricular dysfunction after STEMI is EPHESUS (Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study), where eplerenone was found to reduce death, cardiovascular death, and hospitalization for heart failure.
6. **Diabetes control.** The DIGAMI (Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction) study found a significantly lower mortality rate at 1 year compared with standard therapy (8.6% vs. 18.0%; $p = 0.020$) in diabetic patients treated with aggressive blood glucose reduction with an insulin infusion during hospitalization, followed by multidose subcutaneous insulin injections. However, a small trial (OASIS-6 GIK) and a large (> 20,000 patients) randomized trial (CREATE-ELCA) failed to show any benefit to glucose–insulin–potassium (GIK) infusions. As a result, it appears prudent to institute sound glucose control, but it is not necessary to aggressively pursue glucose control with GIK infusions. Current guidelines suggest insulin therapy

to achieve and maintain blood glucose levels < 180 mg/dL while avoiding hypoglycemia (9).

7. **Antiarrhythmics.** The use of lidocaine or other antiarrhythmic agents is not warranted for the prophylactic suppression of ventricular tachycardia (VT) and fibrillation. Although lidocaine may decrease tachyarrhythmias, there is no survival benefit. There is also evidence to suggest an increase in mortality related to an increased incidence of bradycardia and asystole. In addition, there is evidence that "high-dose" amiodarone may actually increase mortality. Antiarrhythmic therapies are discussed in more detail in Chapter 21.
8. **Intraaortic balloon pump (IABP).** In the treatment of patients with cardiogenic shock, IABP counterpulsation is the preferred means of augmenting systolic pressure because use of an IABP decreases afterload and oxygen requirements while increasing diastolic coronary flow. IABP is contraindicated in the care of patients with marked aortic regurgitation, because it may worsen the regurgitation and cause rapid hemodynamic deterioration (see Chapter 63).
9. **Inotropic agents.** In general, these agents should be avoided whenever possible because of their tendency to increase myocardial oxygen demand and their associated risk of tachycardia and arrhythmias. If IABP counterpulsation proves insufficient, intravenous inotropic support may be warranted, but its use should be guided by means of pulmonary arterial catheter monitoring whenever possible.
   a. **Patients with hypotension accompanied by a pulmonary capillary wedge pressure (PCWP) < 15 mm Hg** should be managed with rapid infusion of boluses of normal saline solution, as should patients with inferior MI who have concomitant RV infarction.
   b. **After intravascular volume has been repleted** and the PCWP is > 15 mm Hg, dopamine may be indicated at doses up to 20 μg/kg/min if hypotension or signs of heart failure persist. Norepinephrine may be used as second-line therapy. The benefits of improved cerebral and systemic perfusion pressure by an increase in inotropy usually come at the cost of increased afterload and myocardial oxygen demand from vasoconstriction.
   c. **Dobutamine** can be useful when PCWP is > 18 mm Hg in the setting of mild to moderate hypotension (70 to 90 mm Hg) or when nitroglycerin or nitroprusside is contraindicated because of the risk of inducing hypotension. Use of PDEs such as milrinone, which have combined vasodilating and inotropic actions, is problematic because of their arrhythmogenicity and their tendency to increase myocardial oxygen consumption. Use of these drugs to maintain adequate systemic pressure and forward output is acceptable if the other therapies have failed. The main goal, however, should be to avoid these agents or reduce the need for them in terms of absolute dose and duration.
10. **Implantable cardioverter–defibrillators (ICDs).** Posited to reduce the risk of sudden death following acute MI, ICDs were routinely implanted an average of 18 days following the index MI event in patients with reduced ventricular function and autonomic dysfunction (DINAMIT trial) (65). Although there was a decrease in cardiovascular death, this study failed to demonstrate any reduction in all-cause mortality. The Multicenter Automatic Defibrillator Implantation Trial II (MADIT II) evaluated the benefit of delayed ICD insertion in patients with prior MI (66). The trial enrolled 1,232 patients with a history of MI at least 1 month prior to enrollment (90 days if bypass surgery was performed) and a left ventricular ejection fraction (LVEF) of ≤ 30%. Patients were randomized to prophylactic ICD insertion or standard medical therapy. At an average follow-up of 20 months, prophylactic insertion of an ICD significantly reduced all-cause

mortality (14.2% vs. 19.8% for standard therapy; HR 0.69; 95% CI, 0.51 to 0.93; $p = 0.016$) (66). According to current ACC/AHA guidelines, an ICD should be inserted in patients with ventricular fibrillation or hemodynamically significant sustained VT that occurs 48 hours after acute MI, assuming there is no recurrent ischemia or MI (67). Patients with an EF ≤ 35% and NYHA class II or III heart failure secondary to an MI that occurred at least 40 days prior should also receive an ICD (67). In addition, patients who are 40 days post-MI with NYHA class I heart failure and an EF ≤ 30% are candidates for ICD insertion (67). Lastly, any patient with a prior MI, nonsustained VT, EF ≤ 40%, and inducible ventricular fibrillation or sustained VT during an electrophysiological study should receive an ICD (67). Patients who have received CABG should have their LVEF and NYHA functional class reassessed 90 days after the procedure to determine ICD candidacy.

11. **Wearable cardioverter–defibrillators.** Patients who are considered at risk for SCD but do not meet the above criteria, such as patients waiting for reassessment of LVEF after CABG, can be given the option of a wearable cardiac defibrillator as a bridge to ICD implantation or recovery of LVEF. The efficacy of wearable cardioverter–defibrillators was evaluated by a two-component trial consisting of the WEARIT and BIROAD studies (68). The WEARIT study enrolled 177 patients with an LVEF < 30% and NYHA class III or IV heart failure. The BIROAD study enrolled 112 patients with a recent MI or CABG who were considered high risk for SCD but did not meet criteria for or refused ICD implantation. During the 901 patient-month observation period, there were six successful and two unsuccessful defibrillations (68). Both unsuccessful defibrillation attempts were due to the device being worn incorrectly (68). During the study, there were six instances of SCD. Five cases were secondary to the device not being worn and in one case the device was being worn incorrectly (68). While wearable cardioverter–defibrillators are currently not recognized in the ACC/AHA guidelines, there appears to be a benefit in select patients.
12. **Anticoagulation for large anterior wall MIs.** Historical teaching (not based on randomized data) has advocated anticoagulating patients for 6 weeks after a large anterior wall MI, with the goal of preventing LV thrombus development. However, in the era of primary PCI with coronary stenting, this recommendation would necessitate treatment with aspirin, clopidogrel, and coumadin, placing patients at fairly high risk for bleeding. Some clinicians recommend anticoagulation only if there is objective evidence of LV thrombus by echocardiography. Others still recommend empiric anticoagulation, but with a slightly lower target international normalized ratio (1.5 to 2.0).

X. ACUTE MI ASSOCIATED WITH COCAINE ABUSE.

The pathophysiologic process and management of acute MI associated with cocaine use differ from those of classic MI.

A. Pathophysiology

1. **The underlying pathophysiologic factor** in acute MI associated with cocaine abuse is believed to be coronary spasm or thrombus formation caused by α-adrenergic stimulation. This can occur in a normal segment of artery or be superimposed on mild to moderate atherosclerosis. Atherosclerosis is accelerated by chronic cocaine use.
2. **Increased oxygen demand** caused by β-adrenergic stimulation of heart rate and contractility also contributes to the onset of ischemia.

B. Clinical presentation.

Chest pain caused by infarction after cocaine ingestion typically occurs within 3 hours, although it can vary from minutes to days, and depends on the route of administration (median of 30 minutes with intravenous cocaine,

90 minutes with crack smoking, and 135 minutes with nasal inhalation). More than 80% of persons with infarction are also cigarette smokers. Studies with animals have demonstrated a synergistic effect between cigarette smoking and cocaine use.

C. Therapy

1. The **initial management** of ST-segment elevation associated with cocaine use includes the routine administration of aspirin, oxygen, and heparin. Aggressive use of sublingual and intravenous nitroglycerin or intravenous calcium channel blockers is advised in an effort to relieve coronary spasm. Intravenous benzodiazepines should also be given, as they not only relieve cocaine induced chest pain but also improve cardiac hemodynamics (69).
2. **β-Blockers are contraindicated in patients with cocaine-induced acute MI.** Although they block undesirable β-adrenergic effects, these agents allow unopposed α-adrenergic stimulation and have been associated with increased mortality in nonrandomized analyses.
3. **Reperfusion therapy must be considered if vasodilator therapy is unsuccessful** in relieving symptoms and ST-segment changes.
4. **Immediate angiography and mechanical revascularization as appropriate** may be even more beneficial in cocaine-induced MI patients. Many patients who use cocaine have contraindications to thrombolysis, such as severe hypertension or persistent vasospasm without thrombosis, which is not amenable to thrombolytic therapy.

XI. POSTOPERATIVE ACUTE MI

A. Etiology and pathophysiology. Acute MI following noncardiac operations most commonly occurs on the third or fourth postoperative day. Conventional theory was that MI was caused by a combination of increased oxygen demand and arterial shear stress associated with the increased adrenergic drive that accompanies pain and ambulation in the postoperative period. Intravascular volume shifts caused by redistribution of fluids, intravenous administration of fluids, and decreased enteral intake all contribute to the risk of postoperative MI. It is apparent that there is a postoperative inflammatory state associated with hypercoagulability, marked by an increase in fibrinogen and other acute-phase reactants. Recent data would indicate that perioperative management of patients with DESs may be problematic, as risk of stent thrombosis may be speculated to be increased in this milieu, whereas antiplatelet therapies are discontinued to reduce bleeding risks.

B. Therapy. Management is complicated by limitations on the use of fibrinolytic agents and anticoagulant therapies. Therapy relies more heavily on the intravenous use of β-blockers and urgent angiography and mechanical reperfusion. The optimal antiplatelet or anticoagulation regimen for recent (< 1 year) DES patients undergoing noncardiac surgery is not known.

XII. SIMPLIFIED REPERFUSION STRATEGY.

The wealth of data regarding reperfusion strategies and adjunctive therapies in acute MI detailed previously may lead to confusion regarding the optimal approach. Based on guideline recommendations, a simplification of the STEMI management strategy can be achieved.

A. For patients presenting with acute MI where primary PCI is available, a reasonable strategy would involve prehospital administration of aspirin, parenteral anticoagulation, and a platelet $P2Y_{12}$ receptor inhibitor, as well as nitrates and β-blocker therapy if not contraindicated, and immediate transfer to the catheterization laboratory. The decision for GP IIb/IIIa therapy and whether coronary stenting should be performed with BMS or DES should be left at the discretion of the interventional cardiologist. If the patient does not have decompensated heart failure or renal failure, assessment of ventricular function should be performed, allowing risk stratification

and initiation of additional adjunctive therapies such as statins, ACE inhibitors, and aldosterone antagonists.

B. For patients presenting to a hospital where primary PCI is not available, but immediate transfer (medical contact to balloon time < 120 minutes) to a PCI facility is available, a similar strategy is employed, with initiation of aspirin, platelet $P2Y_{12}$ receptor antagonist, anticoagulation, nitrates, and β-blockers prior to transfer, although patients at high risk with potentially longer transfer times may benefit from the addition of GP IIb/IIIa inhibitor or half-dose fibrinolytics plus GP IIb/IIIa inhibitor prior to transfer.

C. If anticipated transfer times will exceed the medical contact-to-PCI time of 120 minutes, then fibrinolytic therapy should be instituted in eligible patients within 30 minutes of medical contact. The choice of UFH or enoxaparin remains operator dependent, with either option reasonable. Among patients receiving fibrinolytics, immediate transfer to a PCI facility is preferable, and early angiography (< 24 hours) is recommended. Full-dose fibrinolytics followed by immediate transfer for coronary angiography should be performed in any patient with cardiogenic shock, severe CHF, or ventricular arrhythmia causing hemodynamic compromise, provided that the patient is a suitable candidate for revascularization.

ACKNOWLEDGMENTS: *The author thanks Drs. Deepak P. Vivekananthan, Michael A. Lauer, and Ryan D. Christofferson for their contributions to earlier editions of this chapter.*

CHAPTER 2

James E. Harvey

Unstable Angina and Non–ST-Segment Elevation Myocardial Infarction

I. INTRODUCTION. **Unstable angina (UA)** and **non–ST-segment elevation myocardial infarction (NSTEMI)** remain leading causes of morbidity and mortality in the United States, accounting for more than 1.5 million hospital admissions in the year 2004 alone. These conditions are part of a continuum of acute coronary syndromes (ACSs) that range from UA and NSTEMI to ST-segment elevation myocardial infarction (STEMI). **The clinical presentation of non–ST-elevation acute coronary syndrome (NSTE-ACS) can be variable**, ranging from **progressive exertional angina** to **postinfarction angina**. Because **NSTEMI is distinguished from UA by the presence of elevated serum levels of cardiac biomarkers**, serial measurements in patients presenting with ACS should be performed. With improvements in the diagnosis and risk stratification of patients with UA and NSTEMI, therapeutic approaches to NSTE-ACS have continued to evolve.

II. CLINICAL PRESENTATION

A. Risk factors

1. **Clinical characteristics indicative of high risk.** Symptoms may include an **acceleration of ischemic symptoms within the preceding 48 hours, angina at rest (> 20 minutes), congestive heart failure (S_3 gallop, pulmonary edema, and rales), known reduced left ventricular (LV) function, hypotension, new or worsening mitral regurgitation murmur, age > 75 years, diffuse ST-segment changes on an electrocardiogram (ECG, ≥ 0.5 to 1 mm), and the presence of elevated serum cardiac biomarkers (typically creatine kinase myocardial band [CK-MB], troponin T, or troponin I)**. Patients at intermediate or low risk have angina of short duration, have no ischemic ST-segment changes on ECG, are negative for cardiac biomarkers, and are hemodynamically stable (Table 2.1).
2. **Electrocardiogram.** The initial ECG can help risk-stratify patients with UA. Ideally, this should be performed within 10 minutes of arrival to the emergency department (ED). Patients with ST-segment deviation (i.e., ST-depression or transient ST-elevation) ≥ 0.5 mm or with pre-existing left bundle branch block (LBBB) are at increased risk for death or myocardial infarction (MI) at 1 year after presentation. ST-segment elevation ≥ 0.5 mm in lead aVR raises the possibility of left main or three-vessel coronary artery disease (CAD). **T-wave inversions alone are generally not predictive of adverse ischemic events**.
3. **NSTEMI.** NSTEMI predicts a poorer prognosis among patients with NSTE-ACS. Multivariate predictors of NSTEMI in patients with ACS include **prolonged chest pain** (> 60 minutes), **ST-segment deviations** (depression or transient elevation), and **new or recent onset of angina** (in the past month). Elevations in the levels of troponin I or troponin T, contractile proteins released

TABLE 2.1 Risk Stratification of Patients with Unstable Angina

High risk[a]	Intermediate risk	Low risk
One of the following must be present:	No high-risk feature but must have one of the following:	No high- or intermediate-risk features present
Accelerating tempo of ischemic symptoms in preceding 48 h	Prior MI, peripheral or cerebrovascular disease	
Prolonged ongoing rest pain (> 20 min): moderate or high likelihood of CAD	Prolonged rest pain (> 20 min) that resolves	Increased frequency or duration of angina
Pulmonary edema: most likely caused by ischemia	Rest angina (> 20 min or relieved with rest or sublingual NTG)	Angina provoked by less exertion
Rest angina with dynamic ST changes ≥ 0.5 mm	Nocturnal angina	New-onset angina (within 2 wk to 2 mo)
New or worsening rales, S_3, or MR murmur	New-onset, severe angina within 2 wk with moderate or high likelihood of CAD	
Hypotension, bradycardia, tachycardia		
Bundle branch block, new or presumed new	T-wave changes	Normal or unchanged ECG
Sustained ventricular tachycardia	Pathologic Q waves or resting ST depression (< 1 mm) in multiple lead groups	
Positive serum cardiac biomarkers	Slightly elevated CK-MB, troponin T, troponin I (e.g., troponin T 0.01 ng/mL but < 0.1 ng/mL)	Normal cardiac markers
	Age older than 70 y	

CAD, coronary artery disease; CK-MB, creatine kinase myocardial band; ECG, electrocardiogram; MI, myocardial infarction; MR, mitral regurgitation; NTG, nitroglycerin.

[a]Risk stratification involves considering clinical characteristics and ECG findings to make early triage decisions.

from necrotic cardiac myocytes, are independently predictive of morbidity and mortality among patients with UA (discussed later). According to the European Society of Cardiology/American College of Cardiology (ESC/ACC), troponin elevations in this clinical setting are, by definition, NSTEMI.

4. **Clinical risk classification systems.** Numerous scores have been derived to facilitate risk assessment and guide medical therapy in patients with NSTE-ACS. It is important to note that these scores can also be used to determine which patients may benefit most from early invasive therapy as opposed to a more conservative approach. The **Braunwald classification system** risk-stratifies patients with UA at presentation (Table 2.2). Braunwald defined UA according to the **characteristics of anginal pain** and the **underlying cause**. Patients with

TABLE 2.2 Braunwald Classification of Unstable Angina

Class	Characteristics[a]
I	**Exertional angina**
	New onset, severe, or accelerated
	Angina of < 2 mo duration
	More frequent angina
	Angina precipitated by less exertion
	No rest angina in the last 2 mo
II	**Rest angina, subacute**
	Rest angina within the last month but none within 48 h of presentation
III	**Rest angina, acute**
	Rest angina within 48 h of presentation
	Clinical circumstances
A	**Secondary unstable angina**
	Caused by a noncardiac condition, such as anemia, infection, thyrotoxicosis, or hypoxemia
B	**Primary unstable angina**
C	**Postinfarction unstable angina**
	Within 2 wk of documented myocardial infarction

[a]This classification can be used for risk stratification. Clinical characteristics at presentation and severity of angina are considered.

increasing Braunwald class have been shown to have increasing risk of recurrent ischemia and death at 6 months. Vital clinical characteristics not included in this classification were age, the presence of comorbid conditions (e.g., diabetes mellitus and renal insufficiency), electrocardiographic criteria, and the presence of positive cardiac markers.

The thrombolysis in myocardial infarction (TIMI) UA risk score, based on the TIMI IIB and ESSENCE trials, incorporates **the combination of age, clinical characteristics, ECG changes, and cardiac markers for risk stratification** (Table 2.3). A higher risk score correlated with an increase in the incidence of death, new or recurrent MI, and recurrent ischemia requiring revascularization. The GRACE prediction score, which incorporates nine clinical variables derived from the medical history and clinical findings on initial presentation and during hospitalization, can be used to estimate the in-hospital and 6-month outcomes for patients hospitalized with any form of ACS. Other risk stratification scores based on the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial and the GUSTO IV–ACS trial (Table 2.4) have also been described. Together, these various clinical risk stratification systems help identify high-risk patients likely to benefit most from more aggressive therapy.

TABLE 2.3 Thrombolysis in Myocardial Infarction Risk Score

Score	Incidence of death, new or recurrent MI, and recurrent ischemia requiring revascularization (%)
0/1	4.7
2	8.3
3	13.2
4	19.9
5	26.2
6/7	40.9

Scoring system

One point when risk factor is present, zero points if absent (a total of seven points are possible): Age > 65 y

- Presence of more than three risk factors for coronary artery disease
- Prior coronary stenosis ≥ 50%
- Presence of ST-segment deviation on admission electrocardiogram
- More than two episodes of angina within the past 24 h
- Prior use of aspirin in past 7 d
- Elevated cardiac markers

B. Demographics. Compared with STEMI, patients with **UA/NSTEMI** tend to be **older** and have a higher incidence of **cardiac risk factors or comorbid conditions (e.g., diabetes, hypertension, and hypercholesterolemia)** and a greater likelihood of **prior MI and revascularization procedures** (i.e., percutaneous coronary intervention [PCI] and coronary artery bypass grafting [CABG]).

C. Signs and symptoms. Chest pain due to UA may be rest pain or may be triggered with minimal exertion and can be new onset or increased in severity and frequency or precipitated with less effort than prior angina. Compared with stable angina, **chest pain in UA** is usually more **severe and protracted**, often requiring several doses of sublingual nitroglycerin or extended periods of rest for relief. UA or NSTEMI cannot be differentiated on the basis of chest pain characteristics or ECG abnormalities alone. **The only way this determination can be made is with evidence of myocardial necrosis by measurement of cardiac biomarkers**.

D. Differential diagnosis. It is vitally important to determine the probability that the chest pain or presenting symptom(s) are caused by ACS resulting from obstructive CAD. The exclusion of other diagnoses that mimic angina such as costochondritis, pneumonia, or pericarditis, as well as other life-threatening conditions such as aortic dissection, pneumothorax, and pulmonary embolus, is essential. Hypertensive urgency or emergency, thyrotoxicosis, systemic infection, anemia due to blood loss, and other precipitating causes of myocardial ischemia and secondary UA should also be sought.

TABLE 2.4 GUSTO Risk Score

Risk score	30-Day mortality rate (%)
0–5	0.4
6–10	2.8
11–15	8.7
16–19	25.0
20–22	41.7

Scoring system	
Points are assigned based on the following criteria:	
Age (y)	Points
50–59	2
60–69	4
70–79	6
80+	8
Clinical history	
Prior heart failure	2
Prior stroke/TIA	2
Prior MI/revasc./chronic angina	1
Vitals and laboratory values	
Heart rate ≥ 90 beats/min	3
Elevated troponin and CK-MB	3
Creatinine > 1.4 mg/dL	2
CRP (μg/L) > 20	2
10–20	1
Anemia	1

CK-MB, creatine kinase myocardial band; CRP, C-reactive protein; GUSTO, Global Utilization of Strategies to Open Occluded Arteries; MI, myocardial infarction; revasc., revascularization; TIA, transient ischemic attack.

E. Physical findings. Physical examination alone is insufficient for the diagnosis of UA. **Signs of heart failure** (elevated jugular venous pressure, S_3), impaired myocardial performance (S_4), or peripheral vascular disease (i.e., bruits over major vessels) may be present. These findings predict a higher likelihood of significant CAD.

III. PATHOPHYSIOLOGY. The pathophysiology of ACS encompasses a complex interplay of plaque erosion or rupture, platelet activation and aggregation leading to thrombus formation, endothelial dysfunction, vasospasm, and vascular remodeling.

A. Plaque rupture. UA, NSTEMI, and STEMI share a common initiating event: atheromatous plaque fissure or rupture. Plaque rupture exposes thrombogenic components stimulating platelet deposition, activation, and aggregation at the site

of injury, followed by activation of the coagulation cascade and thrombus formation. Factors contributing to plaque instability include lymphocyte and macrophage activation and increased inflammation. Ruptured plaques or culprit lesions in patients, even when medically stabilized, tend to progress in comparison with stable lesions. Follow-up angiography of 85 patients with UA who were medically stabilized 8 months after initial presentation revealed that 25% of culprit lesions progressed in disease severity (usually to complete occlusion), compared with 7% of nonculprit lesions. This progression of disease correlated with future cardiac events.

B. Thrombus formation. Exposure of circulating platelets to subendothelial contents results in platelet adhesion, aggregation, and, ultimately, thrombus formation. With platelet activation, the glycoprotein (GP) IIb/IIIa receptor on the platelet surface undergoes a conformational change, facilitating further platelet activation and aggregation. This markedly increases thrombin production, further expanding and stabilizing the thrombus.

C. Vasospasm can be induced by the local production of vasoactive substances released from the subendothelial matrix or propagating thrombus or it can occur as a primary phenomenon. Severe localized spasm of a coronary artery segment (i.e., Prinzmetal's angina) may also result in ACS. This vasospasm frequently occurs at sites of unstable plaque and is thought to contribute to thrombus formation. Even angiographically normal coronary arteries with underlying endothelial dysfunction may be subject to vasospasm.

D. Multiple lesions. Although a single culprit lesion is often found at angiography, multiple culprit lesions are not uncommon in patients presenting with UA/NSTEMI, attesting to the global nature of the disease. In a substudy of patients with NSTEMI, **multiple apparent culprit lesions were found in 14% of patients**, whereas a single culprit lesion was found in 49%. An intravascular ultrasound study of patients with NSTEMI undergoing angiography and possible PCI revealed an average of 2.1 plaque ruptures per patient, with 79% of patients having a lesion in a location different from that of the culprit lesion.

E. Secondary causes. UA can also result from a supply–demand mismatch of oxygen delivery to the myocardium. With stable obstructive coronary lesions, precipitants of UA include **increased myocardial oxygen demand** (i.e., tachycardia, severe hypertension, cocaine use, hyperthyroidism, fever, or sepsis) and **decreased oxygen supply** (i.e., anemia or hypoxemia).

IV. INITIAL EVALUATION AND MANAGEMENT

A. Initial triage and clinical assessment recommendations

1. Patients with symptoms suggestive of ACS should be instructed to call 911 immediately. It is recommended that the patient be transported to the hospital by ambulance rather than by friends or relatives.
2. Prehospital emergency service providers should give 162 to 325 mg of aspirin to patients who have symptoms suggestive of ACS, unless it is contraindicated. The patient should be instructed to chew the aspirin rather than swallow it whole so as to facilitate rapid absorption.
3. Patients who have been prescribed nitroglycerin should be instructed to take only one dose in response to chest pain. If the symptoms have not improved or are worsening within 5 minutes, then the patient should call 911 immediately before taking additional nitroglycerin. If the patient is known to have chronic stable angina and the chest pain is significantly improving after taking a dose of nitroglycerin, it is appropriate to instruct the patient to take additional doses of nitroglycerin every 5 minutes for a total of three doses and then call 911 if symptoms have not completely resolved.

4. Patients with suspected ACS who have had anginal symptoms at rest for greater than 20 minutes, hemodynamic instability, or recent syncope should be referred immediately to the ED.

B. Early risk stratification recommendations

1. Patients who present with suspected ACS should be quickly assessed and should undergo early risk stratification for adverse cardiovascular events. This should include a history and physical examination focused on high-risk features of ACS (prolonged chest pain at rest, syncope, signs of CHF, etc.), an ECG, and laboratory biomarkers of cardiac injury, preferably troponin I or T.
2. **A 12-lead ECG should be performed immediately upon arrival at the ED, with the standard being within 10 minutes of arrival for patients with symptoms suggestive of ACS.**

   Common ECG findings in UA/NSTEMI include ST-segment depression, transient ST-segment elevation, and T-wave inversion. However, approximately 20% of patients with an NSTEMI confirmed by cardiac enzymes have no ischemic ECG changes. Moreover, a "normal" ECG pattern is not sufficient to rule out ACS in patients with chest pain (> 4% of patients presenting with chest pain and normal ECG patterns are diagnosed with UA). Persistent ST-segment elevation of ≥ 1 mm in two or more contiguous leads or new LBBB suggests acute STEMI and should be considered for emergency reperfusion therapy (see Chapter 1). As previously mentioned, ST-segment elevation ≥ 0.5 mm in lead aVR raises the possibility of left main or three-vessel CAD. T-wave inversions are the least specific of ECG changes in ACS. However, new, deep, symmetric T-wave inversions of ≥ 2 mm across the precordium in patients presenting with UA (Wellens' syndrome) often correspond to acute ischemia, usually related to a severe proximal left anterior descending artery stenosis. In this setting, revascularization often results in improved ventricular function and normalization of the ECG.
   a. Older classification systems recognized NSTEMI as non–Q-wave MI because myocardial necrosis occurs without ECG evidence of transmural injury. Because of the inability to determine the transmural extent of myocardial injury based on the presence or absence of ST-segment elevation, NSTEMI has become the preferred terminology.
   b. Analysis of 1,473 UA or NSTEMI patients in the **TIMI III trial** revealed transient ST-segment elevation in 10%, ST-segment depression in 33%, T-wave inversion in 46%, and no ischemic ECG changes in 9%.
3. **In patients in whom the initial ECG is not diagnostic** but the anginal symptoms persist, serial ECGs should be performed in 15- to 30-minute intervals. This is done in order to detect the development of ST-segment depression or elevation. Posterior circulation ischemia/infarction should be suspected and the use of posterior ECG leads and echo imaging should be considered.
4. Cardiac biomarkers should be measured in all patients presenting with symptoms suggestive of ACS. The preferred and recommended biomarker is a cardiac-specific troponin (troponin I or T). Patients with negative cardiac biomarkers within 6 hours of symptom onset should have the biomarkers remeasured at 8 to 12 hours after the onset of symptoms.
   a. **Troponins.** Cardiac troponin I and T are contractile proteins found only in cardiac myocytes and are the preferred assays to document the presence of cardiac necrosis. Many clinical trials have used troponin levels for diagnosis and prognosis in ACS. Serum levels of troponins I and T typically rise within 3 to 12 hours after myocardial necrosis and remain elevated afterward for much longer than creatine kinase (CK; 10 to 14 days). Although troponins are more sensitive and specific for myocardial injury than CK and CK-MB, elevated troponin levels can be seen in other nonischemic cardiac conditions

(advanced heart failure and acute pericarditis) and in the setting of renal insufficiency. In the setting of NSTE-ACS, troponins have important prognostic significance beyond that specified by clinical criteria, with elevated levels portending a worse prognosis. In the **GUSTO IIb** trial of patients with UA, the 30-day mortality rate for patients with an elevated troponin T level (> 0.1 ng/mL) was 11.8%, compared with 3.9% for patients with normal troponin levels. Elevated troponin levels in the setting of NSTE-ACS have also been associated with increased likelihood of multivessel disease, high-risk culprit lesions, and intracoronary thrombus visible at the time of angiography.

b. Creatine kinase. Among the most commonly used biochemical markers for the evaluation of patients with suspected ACS are CK and the MB isoenzyme of CK, measured serially every 6 to 8 hours for the first 24 hours. Total CK levels **peak at 12 to 24 hours** after the onset of symptoms, and **CK-MB levels peak at 10 to 18 hours** after the onset of symptoms. The CK-MB isoenzyme is more specific and more sensitive than the total CK measurement for documenting myocardial necrosis. Although a low level of CK and CK-MB is usually found in normal patients, values above the upper limit of normal for a given laboratory suggest the presence of myocardial necrosis. **Many nonischemic conditions, such as pericarditis, skeletal muscle injury, and renal failure**, can cause elevations of total CK levels or, less likely, an increase in CK-MB.

5. The initial evaluation should include consideration and appropriate evaluation of noncoronary causes of the unexplained symptoms (see Section **II.D**).

C. Recommendations for immediate management and triage. The initial management of patients with suspected ACS is dependent on the predicted risk of adverse cardiovascular outcomes. Patients can be initially categorized as low, intermediate, or high risk depending on the historical and clinical findings (Table 2.1). The use of risk stratification models such as the TIMI (Table 2.3), GRACE, and PURSUIT risk scores can also assist in determining which patients are at increased risk.

Patients with probable or possible ACS whose initial 12-lead ECG and cardiac biomarker levels are normal should be monitored on telemetry. Repeat ECGs and repeat cardiac biomarker measurements should be performed at scheduled intervals 6 to 8 hours apart.

1. In **low- and intermediate-risk patients** (Table 2.1) whose serial ECGs and cardiac biomarkers are normal, a conservative strategy may be considered and a **cardiac stress test** should be performed in the ED or monitoring facility. For low-risk patients, it is also appropriate to consider performing the stress test as an outpatient within 72 hours. The optimal time for testing may be determined at the discretion of the physician and in consideration of the patient's wishes. For such patients who are referred for outpatient stress testing, the initiation of antiplatelet and anti-ischemic pharmacotherapy (nitroglycerin and β-blockers) should be strongly considered.

2. **High-risk patients** (Table 2.1) and low-risk patients who have a positive stress test with high-risk features should be admitted to the hospital for inpatient management. Patients with active ongoing ischemia or hemodynamic or electrical instability should be admitted to the intensive care unit.

3. **Noninvasive stress testing.** Stress testing has been thought to be contraindicated in the evaluation of patients with UA because of the concern for acute occlusion with increased cardiac workloads in the presence of unstable plaques. However, patients at low or even intermediate risk who remain pain free for at least 12 to 24 hours and without any symptoms of heart failure can safely undergo functional testing. Intermediate-risk patients include those with age > 70 years; slightly elevated cardiac biomarkers (e.g., troponin T > 0.01 ng/mL but

< 0.1 ng/mL); T-wave changes; pathologic QS; minimal resting ST-depression (< 1 mm) on ECG; rest angina or present with atypical symptoms; and prior history of MI, CABG, peripheral or cerebrovascular disease, or aspirin use.

a. Patients who have **normal myocardial perfusion scan** without fixed or reversible perfusion defects can be safely **discharged** from the hospital and followed up on an outpatient basis. However, **cardiac catheterization** should be considered for patients found to have high-risk features on stress testing because they are at increased risk for adverse ischemic events.

b. If patients are unable to exercise, **pharmacologic stress testing** can be performed instead with dobutamine or a vasodilator such as adenosine or regadenoson. However, no large-scale studies using these modalities for stress testing have been performed in this patient population.

V. EARLY HOSPITAL CARE. The mainstay of treatment for ACS is directed at anti-ischemic therapy and antithrombotic (antiplatelet and anticoagulation) therapy. In clinical practice, the choice of specific antithrombotic therapy is partly determined by whether an initial conservative or an initial invasive approach is planned.

A. Anti-ischemic therapy. All patients admitted to the hospital with ACS should have their activity limited to bed or chair rest to help maintain minimal myocardial demand. Continuous ECG monitoring (telemetry) is recommended, and supplemental oxygen should be provided for patients who are in respiratory distress or have an oxygen saturation < 90%. The following anti-ischemic medications should also be considered.

1. **Nitrates.** Despite a lack of randomized clinical trial data, nitrates remain the mainstay of treatment for patients with UA with chest pain or spontaneous ischemia.

   a. **Dosing.** Sublingual nitroglycerin or nitroglycerin spray (0.4 mg) should be administered immediately and repeated every 5 minutes (three times) to relieve anginal discomfort. If angina persists, intravenous nitroglycerin may be started (at 10 to 20 μg/min). Intravenous nitroglycerin can be quickly titrated (5 to 10 μg/min increases every 5 to 10 minutes) to relieve angina. Caution must be exercised as it may cause profound hypotension. Topical (nitroglycerin transdermal patch, 0.2 to 0.6 mg/h, or nitropaste, 1 to 2", replaced every 6 hours) or oral (isosorbide dinitrate, 10 to 40 mg orally three times daily, or isosorbide mononitrate, 30 to 120 mg orally each day) nitrates can also be used in patients to prevent recurrent anginal symptoms. Tolerance to nitrates is dose and interval dependent and can occur within 24 hours of initiation, requiring higher doses of nitrates. After symptoms are controlled, changing from intravenous to topical or oral formulations with nitrate-free intervals can limit this phenomenon.

   b. **Contraindications.** Contraindications are known **hypersensitivity to nitrates and hypotension. Sildenafil (Viagra) use** within the prior 24 hours has been associated with hypotension, MI, and death.

2. **β-Blockers.** β-Blockers may relieve myocardial ischemia by lowering myocardial oxygen demand through its effects on blood pressure, heart rate, and contractility. A meta-analysis of 4,700 patients with UA and impending MI showed that β-blockers reduced the risk of MI, but no clear effect on mortality was seen. The goals of therapy are a resting heart rate of usually 50 to 60 beats/min and relief of angina. Cardioselective β-blockers (e.g., metoprolol and atenolol) are typically used to minimize side effects.

   a. **Dosing.** Patients with ongoing anginal pain or persistent hypertension can initially be treated with intravenous β-blockers. Intravenous metoprolol can be given in 5-mg increments every 5 to 10 minutes until the desired heart rate and blood pressure response is achieved. Oral metoprolol therapy can

then be started at a dose of 25 to 50 mg every 6 to 12 hours and can be subsequently titrated as necessary.

b. **Contraindications.** Contraindications to β-blocker therapy include **advanced atrioventricular block, active bronchospasm, cardiogenic shock, hypotension, baseline bradycardia,** and **congestive heart failure**.

3. **Calcium channel blockers.** Calcium channel blockers have diverse physiologic effects, including vasodilation, decreased or slowed atrioventricular conduction, and negative inotropy and chronotropy. A meta-analysis of calcium channel blocker trials in the management of UA showed no effect on death or nonfatal MI. However, short-acting nifedipine increased the risk of MI or recurrent angina compared with metoprolol. Diltiazem may reduce adverse events among patients with UA with normal LV function. However, patients with LV dysfunction or pulmonary congestion on physical examination are reported to have worse outcomes when treated with diltiazem.

   a. **Indications.** Calcium channel blockers are recommended for patients with UA, but **only in patients with contraindications to β-blockers or when β-blockers and nitrates fail to fully relieve symptoms of ischemia**. Calcium channel blockers are preferred in patients with variant angina or cocaine-induced vasospasm.

   b. **Contraindications.** Contraindications to calcium channel blockers include LV dysfunction or signs and symptoms of congestive heart failure, hypotension, or atrioventricular conduction abnormalities.

4. **Angiotensin-converting enzyme (ACE) inhibitors.** In patients with LV dysfunction, ACE inhibitors improve survival and ventricular remodeling. The effects of ACE inhibitors in the care of patients with UA or NSTEMI are less well defined. However, **if patients have LV dysfunction, ACE inhibitors should be added to existing medical therapy**. Moreover, in the long term, ACE inhibitors should be considered in every patient with UA/NSTEMI, especially given the overall favorable data for their use in patients with CAD.

B. **Initial conservative versus initial invasive strategy.** Two approaches to managing patients with NSTE-ACS have evolved. Based on a host of factors, including an overall assessment of patient risk, a decision to pursue either an early invasive strategy or an initial conservative strategy needs to be made early in the management of NSTE-ACS (Table 2.5). Overall, patients selected to have early invasive therapy will have coronary angiography performed within 24 hours of admission, or sooner, depending on the clinical situation. Those patients elected to a conservative strategy are managed with optimal medical therapy and undergo angiography only in select circumstances such as development of recurrent symptoms or objective evidence of ischemia while on appropriate medical therapy. There have been several studies comparing these two strategies. Bavry et al. performed a contemporary meta-analysis of seven randomized trials evaluating an early invasive versus a conservative approach in the management of patients with NSTE-ACS. In this pooled analysis of 8,375 patients, there was a 25% relative reduction in all-cause mortality at 2 years with use of early invasive as compared with conservative therapy (4.9% vs. 6.5%, $p = 0.001$). Early invasive therapy also reduced the incidence of nonfatal MI and rehospitalization for UA by 17% and 31%, respectively.

1. The 2011 UA/NSTEMI ACC/AHA guidelines provide specific treatment strategies for the following patient populations:

   a. Patients who have **refractory angina despite medical therapy, hemodynamic instability, or electrical instability** are recommended to undergo an **early invasive strategy**.

   b. For patients who are **initially stabilized but are at high risk for adverse events**, it is reasonable to undergo an **early invasive strategy *or* an initially**

TABLE 2.5 Initial Management Strategy in NSTE-ACS: Early Invasive versus Conservative (Selective Invasive) Approach

Early invasive	Conservative
Hemodynamic instability	Low risk score (e.g., TIMI, GRACE, and PURSUIT)
Arrhythmia instability	Physician or patient preference in low- to intermediate-risk patient
High risk score (e.g., TIMI, GRACE, and PURSUIT)	
Elevated troponin T or I	
Refractory angina despite aggressive medical therapy	
Prior PCI within 6 mo or prior CABG	
Signs or symptoms of congestive heart failure	
New or worsening mitral regurgitation	
Left ventricular function < 40%	

CABG, coronary artery bypass grafting; GRACE, Global Registry of Acute Coronary Events; NSTE-ACS, non–ST-elevation acute coronary syndrome; PCI, percutaneous coronary intervention; PURSUIT, Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy; TIMI, thrombolysis in myocardial infarction.

conservative strategy. This includes patients who are troponin positive. The decision of which strategy to employ should be based upon both physician and patient preference.

c. For patients who are **not at high risk**, it is reasonable to proceed with a **delayed invasive approach**.

d. **Women with low-risk features** are recommended to proceed with a **conservative strategy**.

e. For patients with **extensive comorbid conditions** (e.g., cancer and liver or pulmonary failure), **an early invasive strategy is not recommended**. This is particularly true when the risks of revascularization are likely to outweigh the benefits.

f. It is **not recommended to proceed with an early invasive strategy** in patients with **acute chest pain and a low likelihood of ACS**.

g. Patients who are **not willing to undergo coronary revascularization should not undergo an early invasive strategy**.

2. **Randomized trials.** The following is a summary of the randomized trials that have compared an early invasive versus an early conservative approach in different patient populations.

a. Two earlier trials performed prior to the current era of antiplatelet therapy and coronary stenting were the **TIMI IIIB** and **VANQWISH** trials. Both of these trials showed similar long-term outcomes (death or MI) between early invasive and conservative treatment strategies; however, there was an increase in early mortality associated with invasive therapy in the VANQWISH study,

and these two trials were excluded from the recent meta-analysis, since both are noncontemporary.

b. In the **FRISC II** trial, patients with UA/NSTEMI were randomized in a factorial design to an early invasive or conservative strategy and to dalteparin or placebo. An early invasive strategy was associated with a reduction in the rate of death or MI at 6 months (9.4% vs. 12.1%, $p = 0.031$) and reduced symptoms of angina and rehospitalization, regardless of treatment with dalteparin.

c. In the **TACTICS-TIMI 18** trial, patients with UA/NSTEMI treated with aspirin, heparin, and tirofiban were randomized to an early invasive or a conservative strategy. Patients assigned to an **early invasive approach underwent catheterization within 4 to 48 hours**, with revascularization as appropriate. Patients assigned to the conservative arm underwent cardiac catheterization only if there was objective evidence of recurrent ischemia or abnormal stress test. An early invasive strategy was associated with a reduction in the composite of death, nonfatal MI, or rehospitalization for ACS at 6 months (15.9% vs. 19.4%, $p = 0.025$), as well as a reduction in the incidence of death or nonfatal MI at 6 months (7.3% vs. 9.5%, $p < 0.05$).

d. In the **RITA 3** trial, an early invasive strategy for moderate-risk patients with UA/NSTEMI was associated with a decreased rate of death, MI, or refractory angina compared with conservative therapy at 4 months (9.6% vs. 14.5%, $p = 0.001$). This was caused primarily by a reduction in refractory angina. These results suggest that even in moderate-risk patients, an early invasive strategy may be preferred. The RITA 3 investigators also reported a meta-analysis of trials comparing an early invasive versus a conservative approach, with an association between the early invasive approach and a decreased incidence of death or nonfatal MI at 1 year (relative risk [RR] = 0.88, 95% confidence interval [CI]: 0.78 to 0.99).

e. In the **ISAR-COOL** trial, patients with UA/NSTEMI treated with intensive medical therapy (aspirin, heparin, clopidogrel [600-mg loading dose], and tirofiban) were randomized to immediate invasive therapy (median time of 2.4 hours) versus delayed invasive therapy after a "cooling off" period (median time of 86 hours). Those who had early intervention had a significant reduction in death or MI at 30 days compared with those who had a "cooling off" period (5.9% vs. 11.6%, $p = 0.04$).

f. In the **ICTUS** trial, 1,200 patients with NSTE-ACS with elevated troponins were randomized to either early invasive therapy (angiography within 24 to 48 hours) or initial conservative strategy with selective invasive therapy. There was no difference in the primary composite end point of death, MI, or rehospitalization for ACS at 1 year between the two groups (22.7% vs. 21.2%, $p = 0.33$). The aggressive medical therapies and high rates of revascularization (47%) in the initial conservative strategy group are two among many potential explanations for the findings of this trial.

g. In the **TIMACS** trial, patients with NSTEMI presenting within 24 hours of onset of symptoms were randomized to undergo angiography as soon as possible (within 24 hours) or after a minimum delay of 36 hours. These patients received contemporary medical therapy including acetylsalicylic acid (ASA), clopidogrel (>80%), heparin or fondaparinux, and GP IIb/IIIa inhibitors (23%). Overall, there was a nonsignificant trend toward a reduction in death, new MI, or stroke at 6 months for patients who received an early invasive strategy (11.3% for delayed angiography vs. 9.6% in the early intervention, $p = 0.15$). However, there was a significant reduction in the secondary end point of death, MI, or refractory ischemia for patients randomized to an early invasive strategy (12.9% vs. 9.5%, $p = 0.003$) that was primarily driven

by a decrease in refractory ischemia. Interestingly, patients who were in the highest tertile of risk according to the GRACE score were the most likely to benefit from an early invasive strategy. Overall, this study supports an early invasive strategy for patients presenting with UA/NSTEMI, particularly for those among the highest tertile of risk according to the GRACE scale.

h. The **ABOARD** trial assessed whether a very aggressive strategy of emergent intervention (analogous to primary PCI for STEMI) would benefit patients presenting with UA/NSTEMI versus delayed angiography and intervention. Immediate angiography and intervention did not decrease the rate of the primary outcome of median troponin I release (2.1 ng/mL for the invasive strategy vs. 1.7 ng/mL for the delayed strategy) nor did it show a trend toward improved outcomes in the secondary end point of death, MI, or urgent revascularization at 1 month (13.7% for early invasive management vs. 10.2% for the conservative approach, $p = 0.31$).

C. Antiplatelet and anticoagulant therapies. There are many different antiplatelet and antithrombotic agents currently available for the treatment of ACS. As such, the decision of which combination of medications to use and when to administer them can be challenging. In general, the decision of which agents to use depends on (1) whether an early invasive strategy is used and (2) what post-angiography management strategy is employed. Regardless of which strategy is chosen, all patients presenting with ACS should receive a loading dose of aspirin (162 to 325 mg) to be chewed and swallowed; if the patient is aspirin intolerant, then a loading dose of clopidogrel (300 to 600 mg) should be given. The antiplatelet and anticoagulant therapies available for each of the following strategies are listed below. The specific doses, adverse effects, and pharmacokinetics of these agents are then listed separately.

1. **Initial conservative strategy.** After receiving aspirin, patients who undergo an initial conservative strategy should receive an **anticoagulant** and be started on **clopidogrel** therapy. Enoxaparin and fondaparinux are the anticoagulants of choice; unfractionated heparin (UFH) is an acceptable alternative. Of note, if fondaparinux is used and an invasive strategy is ultimately employed, then another anticoagulant with factor IIa activity (UFH) must be coadministered to prevent catheterization-associated thrombosis.
2. **Initial invasive strategy.** After receiving aspirin, patients who undergo an initial invasive strategy should receive **anticoagulation with enoxaparin, UFH, or bivalirudin**. Before proceeding with catheterization, it is recommended to administer a **second antiplatelet agent**. These agents include clopidogrel or ticagrelor. Prasugrel may also be utilized after angiographic definition. A GP IIb/IIIa inhibitor such as eptifibatide or tirofiban may be considered.
3. **Once angiography is performed, the appropriate subsequent therapy depends on the management plan.**
   - **a.** For patients undergoing **CABG surgery**, it is recommended to **continue aspirin therapy**. If clopidogrel therapy has been started, it should be discontinued 5 days prior to CABG. GP IIb/IIIa inhibitors should be discontinued 4 hours prior to CABG. Although ticagrelor is a reversible $P2Y_{12}$ inhibitor, bleeding rates were similar to clopidogrel following CABG when discontinued 5 days prior to surgery. Bleeding rates following CABG were greater with prior exposure to prasugrel compared with clopidogrel in the TRITON–TIMI 38 trial and the risk persisted for up to 7 days from last drug exposure. UFH can be continued until CABG; however, enoxaparin should be discontinued 12 to 24 hours prior to CABG and bivalirudin should be discontinued 3 hours prior to CABG.
   - **b. Percutaneous coronary intervention.** All patients undergoing PCI should be on dual antiplatelet therapy. Routine GP IIb/IIIa inhibitor prior to PCI is not warranted and may be used adjunctive to PCI in selective cases.

c. **Medical therapy.** If the catheterization reveals no significant obstructive CAD, then the antiplatelet and anticoagulant therapy is to be continued at the discretion of the physician. If catheterization reveals significant CAD that is to be medically managed, then it is recommended to continue aspirin therapy and to load with clopidogrel therapy if not done so prior to catheterization. GP IIb/IIIa therapy should be discontinued. UFH should be continued for 48 hours; enoxaparin or fondaparinux should be continued for the duration of the hospitalization. Bivalirudin should be continued for 72 hours.

4. **Aspirin.** Despite being a relatively weak inhibitor of platelet aggregation, aspirin has a significant effect on mortality in UA. There are several pathways that lead to platelet activation, of which aspirin blocks only the cyclooxygenase-derived thromboxane A_2 pathway. Aspirin therapy for UA/NSTEMI has been studied in five major clinical trials at doses ranging from 75 to 325 mg/d. Overall, treatment with aspirin reduced the combined end point of death or nonfatal MI by 50%.
   a. **Pharmacokinetics.** The onset of aspirin's antiplatelet effect is quite rapid, with substantial inhibition of thromboxane A_2 production within 15 minutes, translating into measurable platelet inhibition within 60 minutes. It should be given as soon as patients present with ACS. Because aspirin's inhibition of cyclooxygenase is irreversible, its antiplatelet effect is durable, lasting 7 to 10 days.
   b. **Dosing.** Unless contraindicated (e.g., active bleeding and documented hypersensitivity to aspirin), an initial dose of 162 to 325 mg of nonenteric-coated aspirin (chewed and swallowed) should be given to all patients with suspected UA. Those patients allergic or intolerant to aspirin should receive clopidogrel as soon as possible. For patients who undergo PCI, aspirin at 162 to 325 mg/d is recommended for at least 1 month after bare-metal stent (BMS), 3 months after sirolimus-eluting stent implantation, and 6 months after paclitaxel-eluting stent implantation followed by 81 to 162 mg/d indefinitely thereafter. Subsequent daily aspirin doses can be reduced, with the preferred dose for secondary prevention being 81 to 162 mg daily; this should be continued indefinitely.
5. **Ticlopidine.** Ticlopidine was the first commercially available thienopyridine. Ticlopidine and the other thienopyridines inhibit adenosine diphosphate–induced platelet aggregation. Compared with placebo, ticlopidine reduced rates of death or MI at 6 months among patients with UA to a degree similar to that of aspirin. Ticlopidine is associated with a 1% to 5% increase in neutropenia and is thus no longer recommended as a first-line thienopyridine in patients who present with UA/NSTEMI. It is now reserved for patients in whom clopidogrel or prasugrel is not tolerated or contraindicated.
   a. **Pharmacokinetics.** Ticlopidine's onset of action is delayed, usually taking 2 to 3 days for maximum antiplatelet effect.
   b. **Side effects.** Ticlopidine can cause neutropenia (1% to 5% of patients) and is rarely associated with thrombotic thrombocytopenic purpura (TTP).
   c. **Dosing.** Ticlopidine is given as a loading dose of 500 mg followed by 250 mg twice daily.
6. **Clopidogrel.** Clopidogrel was the second commercially available thienopyridine and is the most extensively studied member of this group. In the CURE trial, patients with UA or NSTEMI had a lower rate of cardiovascular death, nonfatal MI, or stroke when treated with aspirin and clopidogrel versus aspirin alone (9.3% vs. 11.4%, $p < 0.001$). Patients treated with this combination experienced lower rates of refractory ischemia, heart failure, or revascularization. However, an increased rate of major bleeding (3.7% vs. 2.7% for aspirin) was seen in

patients receiving clopidogrel, predominantly in those undergoing CABG. In a substudy of the CURE trial, PCI-CURE, pretreatment with clopidogrel resulted in lower rates of cardiovascular death, nonfatal MI, or urgent target-vessel revascularization at 30 days (4.5% vs. 6.4%) in patients with UA/NSTEMI undergoing PCI. Long-term treatment with clopidogrel resulted in lower rates of cardiovascular death, nonfatal MI, or revascularization, without a significant increase in major bleeding. The benefit of clopidogrel pretreatment in PCI was further confirmed in the CREDO trial in which patients receiving a 300-mg loading dose plus 1 year of 75 mg daily maintenance therapy of clopidogrel had a 26.9% relative reduction in death, nonfatal MI, or stroke at 1 year compared with those receiving only 1 month of maintenance therapy without any loading dose of clopidogrel.

a. **Pharmacokinetics.** Clopidogrel is a prodrug that is metabolized to a pharmacologically active metabolite. Clopidogrel has a shorter onset of action than ticlopidine when 300 mg is given, with antiplatelet activity being detected within 2 hours after administration. Loading with 600 mg has been shown to have an even more rapid onset of action.
b. **Side effects.** Clopidogrel is generally well tolerated. Rarely, it can cause an allergic reaction typically resulting in diffuse urticaria. There have also been case reports of TTP with clopidogrel therapy.
c. **Dosing.** The conventional loading dose for clopidogrel has been 300 mg; however, recent evidence demonstrates a more rapid and heightened platelet inhibitory response, resulting in decreased ischemic events after PCI with use of a 600-mg loading dose of clopidogrel. The CURRENT OASIS-7 trial found that patients presenting with ACS who ultimately undergo PCI have a lower rate of cardiovascular death, MI, and stroke when loaded with 600 mg versus 300 mg. This decrease in ischemic end points came at the cost of an increase in major bleeding. Clopidogrel maintenance therapy is 75 mg daily.

7. **Prasugrel.** Prasugrel is the most recently commercially available thienopyridine. In preclinical studies, prasugrel has been shown to have a more potent antiplatelet effect than clopidogrel. The TRITON–TIMI 38 trial evaluated the efficacy of prasugrel versus clopidogrel in patients presenting with ACS with planned PCI. In this study of 13,608 patients, use of prasugrel as compared with clopidogrel resulted in a significant reduction in the primary efficacy end point of death from cardiovascular causes, nonfatal MI, or nonfatal stroke (9.9% vs. 12.1%, $p < 0.001$). However, the salutary benefits in reduction of ischemic events with prasugrel came at the expense of an increase in late bleeding events, including a significant increase in rates of both major bleeding (2.4% vs. 1.1%, $p = 0.03$) and fatal bleeding (0.4% vs. 0.1%, $p = 0.002$). It is an absolute contraindication to use prasugrel in patients with a history of transient ischemic attack or stroke and a relative contraindication in patients ≥ 75 years of age or < 60 kg due to the absence of a net favorable benefit or even a harmful effect in these patient subgroups.

a. **Pharmacodynamics.** Like clopidogrel, prasugrel is a prodrug and is rapidly metabolized to a pharmacologically active metabolite and inactive metabolites. After a 60-mg loading dose of prasugrel is given, 90% of patients achieve ≥ 50% inhibition of platelet aggregation within 1 hour, with maximum achieved platelet inhibition being approximately 80%. The mean steady-state inhibition of platelet aggregation with prasugrel is 70% after 3 to 5 days of treatment. Platelet aggregation returns to baseline 5 to 9 days after discontinuation of therapy.
b. **Side effects.** Similar to clopidogrel, prasugrel is generally well tolerated. Allergic reactions to prasugrel are rare; however, bleeding-related complications such as epistaxis or easy bruising are not uncommon.

c. **Dosing.** The loading dose for prasugrel is 60 mg followed by a maintenance dose of 10 mg/d.

8. **Ticagrelor.** Ticagrelor is a recently FDA-approved reversible non-thienopyridine $P2Y_{12}$ receptor antagonist. Unlike clopidogrel and prasugrel, ticagrelor is not a prodrug and does not require bioactivation. In the PLATO trial involving patients presenting with ACS, there was a significant 1.9% reduction in major adverse cardiac events and a significant 1.4% reduction in death for patients who were randomized to receive ticagrelor versus clopidogrel. This came at the cost of an increase in nonprocedural bleeding in patients who were randomized to ticagrelor. In addition, dyspnea was noted in 14% of patients taking ticagrelor.
   a. **Dosing.** The loading dose of ticagrelor is 180 mg followed by a maintenance dose of 80 mg twice daily. Ticagrelor was not FDA approved at the time of the 2011 UA/NSTEMI guidelines, and so it is not currently included in the recommendations.
9. **Heparin.** UFH in combination with aspirin reduces the incidence of ischemic events in patients with UA. A meta-analysis of six trials in patients with UA demonstrated that treatment with aspirin plus UFH reduced the incidence of death or nonfatal MI by 33% compared with treatment with aspirin alone, although this difference did not quite reach statistical significance. The treatment effect of heparin may also wane after therapy is discontinued.
   a. **Duration of therapy.** Although the optimal length of therapy with UFH is unknown, studies have suggested that therapy must be continued for at least 3 to 7 days to achieve clinical benefit. Currently, heparin is discontinued after angiography and PCI are performed.
   b. **Rebound ischemia.** Rebound ischemia is thought to result from the accumulation of thrombin during UFH administration and the ensuing platelet aggregation. Studies have shown that this rebound ischemia can be attenuated with the concomitant use of aspirin.
   c. **Recommendations.** Intravenous UFH can be used for anticoagulant therapy in patients with NSTE-ACS undergoing either an invasive or conservative treatment strategy unless contraindicated (e.g., active bleeding, known hypersensitivity, and history of heparin-associated thrombocytopenia).
   d. **Dosing.** Initially, heparin should be given as a weight-adjusted bolus (60 U/kg), followed with an infusion (15 U/kg/h). The activated partial thromboplastin time (aPTT) should be monitored every 6 hours until it stabilizes between 50 and 70 seconds and monitored subsequently every 12 to 24 hours thereafter. Standardized heparin nomograms have simplified and streamlined the initial orders for UFH and the subsequent adjustment of dosing based on aPTT levels.
10. **Low-molecular-weight heparin (LMWH).** The advantages of LMWH compared with UFH include increased bioavailability, a fixed dosing regimen, more effective thrombin inhibition, lower rates of heparin-induced thrombocytopenia, and cost savings because serial aPTT levels do not have to be monitored.
   a. **Comparison with heparin.** A meta-analysis of 12 trials involving 17,157 patients with UA/NSTEMI that compared the use of several different LMWHs with UFH found no significant benefit with LMWHs compared with UFH (odds ratio [OR] = 0.88, 95% CI: 0.69 to 1.12, $p = 0.34$). In the **ESSENCE** trial, however, patients with UA/NSTEMI had a lower rate of death, MI, or recurrent angina at 30 days when treated with the LMWH, enoxaparin, than with UFH (19.8% vs. 23.3%, $p = 0.016$). Patients treated with enoxaparin also underwent fewer revascularization procedures and experienced similar rates of major bleeding. Similarly, in the **TIMI IIB** study, patients with UA/NSTEMI treated with enoxaparin had a lower rate of death, MI, or urgent revascularization at 43 days compared with those treated

with UFH (17.3% vs. 19.7%, $p = 0.048$). Enoxaparin has been shown to be superior to UFH in this patient population and may be used instead of UFH, unless CABG is anticipated within 24 hours. In the **SYNERGY** trial of 9,978 high-risk patients with NSTE-ACS treated with an invasive therapeutic approach, enoxaparin was found to be noninferior but not superior to UFH. The rate of death or MI at 30 days was 14% in the enoxaparin group and 14.5% in the UFH group ($p = 0.396$). There was an increase in major bleeding per the TIMI criteria in those patients randomized to enoxaparin as compared with UFH (9.1% vs. 7.6%, $p = 0.008$). Post hoc analysis suggested that crossover from enoxaparin to UFH may have partly been the reason for this excess bleeding risk associated with enoxaparin.

b. **Dosing. Enoxaparin** is administered as a 1 mg/kg dose given subcutaneously (SQ) every 12 hours. No routine laboratory values have to be followed. However, in certain clinical settings (e.g., renal insufficiency and severe obesity), an anti-Xa level can be measured. The therapeutic anti-Xa level has yet to be determined in patients with UA/NSTEMI or in patients undergoing PCI, but the commonly accepted therapeutic range is 0.5 to 1.0 anti-Xa units/mL.

c. **Recommendations.** In patients with NSTE-ACS who may undergo either a conservative or an early invasive therapy, enoxaparin is an acceptable agent for anticoagulation.

11. **Direct thrombin inhibitors (DTIs).** DTIs inhibit clot-bound thrombin more effectively than UFH and are not inactivated by plasma proteins or platelet factor 4. Hirudin is an older generation DTI that is no longer used clinically and has been supplanted by its synthetic derivative, bivalirudin.

    a. **Bivalirudin (previously Hirulog).** Bivalirudin is a synthetic derivative of hirudin, with a shorter half-life, that reversibly inhibits thrombin. In the **ACUITY** trial of 13,819 patients with UA/NSTEMI, the clinical efficacy of bivalirudin plus GP IIb/IIIa inhibition was noninferior to heparin plus GP IIb/IIIa inhibition, with 30-day rates of ischemia of 7.7% versus 7.3%, respectively.

        (1) **Recommendations.** Current guidelines recommend bivalirudin as a possible choice for anticoagulant therapy in conjunction with GP IIb/IIIa inhibition or a thienopyridine prior to angiography in patients presenting with NSTE-ACS with a planned invasive therapeutic approach. Bivalirudin is not recommended in those patients determined to undergo an initial conservative approach with medical therapy.

12. **Factor Xa inhibitors.** Fondaparinux is a heparin pentasaccharide analog that selectively inhibits factor Xa in the coagulation cascade. In comparison with UFH, fondaparinux has decreased binding to plasma proteins along with dose-independent clearance with a longer half-life. These properties translate into more predictable and sustained anticoagulation, which permits fixed-dose, once-daily administration.

    a. **Comparison with enoxaparin.** The **OASIS-5** trial evaluated the efficacy of fondaparinux versus enoxaparin in 20,078 patients with UA/NSTEMI. Patients receiving fondaparinux (2.5 mg SQ once daily) had a similar rate of the combined end point of death, MI, or refractory ischemia at 9 days as those randomized to enoxaparin (1.0 mg/kg SQ twice daily). The use of fondaparinux was associated with a lower rate of major bleeding at 9 days as compared with enoxaparin (2.2% vs. 4.1%, $p < 0.001$). However, in this trial, there was an increased incidence of catheter-associated thrombus noted, and the trial protocol was changed to allow for use of open-label UFH, which initially was not allowed during PCI.

    b. **Dosing.** The dosing of fondaparinux for UA/NSTEMI is 2.5 mg SQ once daily. Fondaparinux is renally cleared and its use is contraindicated in those patients with a creatinine clearance (CrCl) < 30 mL/min.

c. **Recommendations.** Fondaparinux can be used for anticoagulant therapy in those patients selected to undergo a conservative medical approach. It is the preferred therapy in patients with increased risk of bleeding being managed with medical therapy. For patients who undergo angiography and PCI, adjuvant UFH is recommended, given the increased rates of catheter-associated thrombus with fondaparinux in the **OASIS-5** trial.

13. GP IIb/IIIa inhibitors

Background. Platelet aggregation requires the activation of GP IIb/IIIa receptors on the platelet surface. The GP IIb/IIIa receptors of adjacent platelets bind fibrinogen molecules that allow cross-linking of the platelets, which subsequently initiates thrombus formation. Blocking the GP IIb/IIIa receptor inhibits platelet aggregation and reduces thrombus formation. **Abciximab**, the Fab fragment of a murine monoclonal antibody to the human GP IIb/IIIa receptor, binds this receptor tightly and inhibits platelet aggregation for days after the drug infusion is discontinued. In addition to its affinity for the GP IIb/IIIa receptor, abciximab inhibits other receptors, including the vitronectin receptor on endothelial cells and the MAC-1 receptor on leukocytes. **Eptifibatide** is a cyclic peptide inhibitor derived from snake venom, with rapid onset and a short half-life. Because of its short half-life, continuous drug infusion is required to sustain maximal inhibition of platelet aggregation. **Tirofiban** may also be utilized.

Use in UA during PCI. Abciximab and eptifibatide have been approved by the FDA for use as adjunctive therapy during PCI. Tirofiban has been approved for the treatment of UA, with continuation of its use into the catheterization laboratory.

a. **Abciximab** was studied in patients with UA undergoing high-risk percutaneous transluminal coronary angioplasty (PTCA) in the Evaluation of 7E3 for the Prevention of Ischemic Complications (**EPIC**) trial. In 489 patients, abciximab lowered major ischemic event rates (12.8% for placebo vs. 4.8% for abciximab, $p = 0.012$) at 30 days, primarily because of a reduced rate of death or MI. This benefit was maintained at long-term follow-up (3 years). In the Evaluation in PTCA to Improve Long-term Outcome with abciximab Glycoprotein IIb/IIIa blockade (**EPILOG**) trial, treatment with abciximab in addition to heparin was associated with a significant reduction in the rate of death, MI, or urgent revascularization at 30 days (11.7% vs. 5.2% in the low-dose heparin group, $p < 0.001$), expanding the benefit to low- and intermediate-risk patients undergoing PCI. In the EPILOG trial, a lower, weight-adjusted dosing algorithm of heparin resulted in similar major and minor bleeding rates between abciximab and placebo. In the c7E3 Fab Antiplatelet Therapy for Unstable Refractory Angina (**CAPTURE**) study, abciximab given 18 to 24 hours before PCI reduced the rate of death, MI, and urgent intervention (10.8% vs. 15.4%, $p = 0.017$). Patients treated with abciximab also had a higher rate of thrombus resolution and improved procedural success. Results from the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (**EPISTENT**) trial demonstrated that when **stents and abciximab** are used together, the rate of adverse ischemic events and long-term (1-year) mortality is lower than that with stents alone. Abciximab (bolus of 0.25 mg/kg abciximab is followed by 12-hour infusion at 10 μg/min) is commonly used during PCI in patients with ACS.

b. **Tirofiban.** In the Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (**RESTORE**) trial, patients presenting with ACS who underwent PCI within 72 hours of presentation were treated with heparin and aspirin with the addition of tirofiban or placebo. Treatment with tirofiban resulted in a reduction in the short-term rate of death, MI, or revascularization for failed PTCA or recurrent ischemia without an increase in major bleeding. In the Platelet Receptor Inhibition in Ischemic Syndrome

Management (**PRISM**) trial, treatment with tirofiban (the dose used was a 0.6 μg/kg/min bolus for 30 minutes, followed by an infusion of 0.15 μg/kg/min) in patients with UA resulted in a 32% decrease in the rate of death, MI, or refractory ischemia at 48 hours (3.8% vs. 5.6%, $p = 0.01$). The composite end point, however, was not significantly different at 30 days, although the mortality was reduced (3.6% vs. 2.3%). Notably, very few patients underwent PCI during the treatment period (1.9%). In the Platelet Receptor Inhibition for Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (**PRISM-PLUS**) trial, tirofiban in addition to heparin was associated with a decreased rate of death, MI, or refractory ischemia compared with heparin alone at 7 days (12.9% vs. 17.9%, $p = 0.004$), at 30 days (18.5% vs. 22.3%, $p = 0.03$), and at 6 months (27.7% vs. 32.1%, $p = 0.02$).

c. **Eptifibatide** was evaluated in the **PURSUIT** trial. Eptifibatide treatment (180 μg/kg bolus followed by an infusion of 1.3 or 2.0 μg/kg/min) in patients with UA/NSTEMI was associated with a decreased rate of death or nonfatal MI at 30 days compared with placebo (14.2% vs. 15.7%, $p = 0.04$), although with an increased rate of bleeding.

d. **Use independently of PCI.** Eptifibatide and tirofiban have been approved for use in the care of patients with UA as a primary medical therapy whether PCI is performed or not. A pooled analysis of the **CAPTURE**, **PURSUIT**, and **PRISM-PLUS** trials revealed that during the study medication infusion, treatment with a GP IIb/IIIa inhibitor resulted in a reduction of death or nonfatal MI of 34% in patients with UA/NSTEMI, suggesting an early benefit during medical treatment that may be independent of its effect during PCI. However, in the **GUSTO IV–ACS** trial, patients with UA/NSTEMI treated with abciximab bolus and infusion for 24 or 48 hours received no benefit in addition to conventional therapy with aspirin and heparin, with the 30-day incidence of death or MI being similar across groups (8.0% placebo, 8.2% for 24-hour infusion, and 9.1% for 48-hour infusion). Medical management was encouraged during the first 48 hours, and only 1.6% of patients underwent PCI while on the study drug. In patients not likely to be treated with an early invasive strategy, abciximab has shown no benefit using the dosing protocol described in that trial.

e. **Recommendations. The benefit of GP IIb/IIIa inhibitors is predominantly in patients who subsequently undergo PCI.** However, in the contemporary era with newer anticoagulant therapies and use of higher loading doses of clopidogrel (600 mg), there is less clarity regarding the utility of adjuvant GP IIb/IIIa inhibition with PCI. The **ISAR-REACT 2** trial randomized 2,022 patients with NSTE-ACS undergoing PCI to abciximab or placebo in addition to pretreatment with a 600-mg loading dose of clopidogrel. Overall, there was a 25% reduction in death, MI, or urgent target-vessel revascularization noted in those patients who received abciximab. However, this benefit was observed solely in those patients with elevated troponin levels. Also, the **ACUITY** trial suggests that GP IIb/IIIa inhibition is unnecessary in those patients who have received bivalirudin plus clopidogrel pretreatment with a loading dose of at least 300 mg at least 6 hours prior to angiography. For patients with UA/NSTEMI undergoing an **early invasive strategy**, the ACC/American Heart Association (AHA) guidelines state that either a GP IIb/IIIa inhibitor or clopidogrel can be used upstream in lower risk patients, whereas combination therapy with both is favorable in patients with high-risk features, with early recurrent ischemic discomfort, or having a delay to angiography. If PCI is likely to be performed and there is no expected delay to angiography, then abciximab can be used upstream for

GP IIb/IIIa inhibition. Otherwise, eptifibatide or tirofiban is the preferred GP IIb/IIIa inhibitor of choice.

f. Subgroups that benefit from GP IIb/IIIa inhibitors

(1) Troponin-positive status. Several studies have shown that the benefit of these agents resides primarily with patients presenting with elevated cardiac troponins. In the **CAPTURE** trial, patients with UA with an elevated troponin T level had a greater reduction in the rate of death or nonfatal MI with abciximab therapy than patients with a normal troponin T level. This continues to be true in the contemporary era of dual antiplatelet therapy with aspirin and clopidogrel, as discussed earlier with the results of the **ISAR-REACT 2** trial. Therefore, elevated troponin levels continue to identify patients at higher risk for adverse cardiac events who may benefit particularly from therapy with GP IIb/IIIa inhibitors.

(2) Diabetics. In a meta-analysis of diabetic patients with ACS, the use of GP IIb/IIIa inhibitors was associated with decreased mortality at 30 days (6.2% vs. 4.6%, $p = 0.007$). In diabetic patients with ACS undergoing PCI, treatment with GP IIb/IIIa inhibitors was associated with a more marked benefit (mortality rate: 4.0% vs. 1.2%, $p = 0.002$). In this same analysis, GP IIb/IIIa inhibitors did not confer the same improvement in mortality to nondiabetic patients (3.0% vs. 3.0%). These data suggest that diabetic patients, in particular, benefit from the use of these agents, when undergoing PCI during the initial hospitalization.

g. Oral GP IIb/IIIa inhibitors. Oral GP IIb/IIIa inhibitors have not been shown to be beneficial and may increase mortality. The reason for this dichotomy between the benefit seen with intravenous GP IIb/IIIa inhibitors and the detriment seen with oral inhibitors is not entirely clear. One possible explanation is that the oral agents, in contrast to the intravenous GP IIb/IIIa inhibitors, have partial agonist activity, which actually leads to an increase in fibrinogen binding and platelet aggregation on administration.

14. Fibrinolytic agents. Although fibrinolytic therapy has decreased mortality and improved LV function among patients with STEMI, the use of these agents is associated with worse outcomes in patients with UA and NSTEMI. A meta-analysis of fibrinolytic therapy in the management of UA demonstrated an increase in death or nonfatal MI in patients receiving fibrinolytics (9.8% for fibrinolytics vs. 6.9% for placebo). The lack of efficacy of fibrinolytic agents in these patients may result from the prothrombotic milieu induced by exposure of clot-bound thrombin after fibrin cleavage. Plasmin generation increases, and platelets are activated, perpetuating this prothrombotic state. Fibrinolytic agents would not be expected to dramatically improve coronary blood flow in UA because of the nonocclusive nature of thrombi in these patients.

VI. HOSPITAL DISCHARGE AND POSTDISCHARGE CARE. The risk of progression to MI or the development of recurrent MI or death is highest during the first two months after UA/NSTEMI. Thus, although patients with UA usually receive definitive therapy during hospitalization, close follow-up care after hospital discharge is imperative. There are no guidelines regarding noninvasive stress testing of patients without symptoms who have undergone percutaneous or surgical revascularization for UA. If anginal symptoms recur after hospital discharge, stress testing or cardiac catheterization can be performed, depending on the clinical presentation. Follow-up must include lifestyle alteration, risk factor modification, and secondary prevention. An exercise regimen in stable patients, smoking cessation efforts, and dietary changes have all been shown to improve outcomes. Hypertension, dyslipidemia, and diabetes mellitus must be diagnosed and aggressively treated. Antianginals (i.e., nitrates, β-blockers, and possibly calcium antagonists) should be used for symptom relief. Patients must be reassured and educated about their

acceptable level of activity. **The long-term use of aspirin, clopidogrel, β-blockers, statins/cholesterol-lowering regimens, and/or ACE inhibitors should not be neglected**. Specific recommendations regarding a secondary prevention postdischarge medication regimen are listed below:

A. **Anti-ischemic medications** that were required to control symptoms during the hospitalization should be continued after discharge in patients who did not undergo coronary revascularization, had an unsuccessful revascularization, or had recurrent angina after revascularization. This will often require additional titration of the antiischemic medications (see Section **VI.A**). All patients should be given clear instructions about what symptoms to look for that are suggestive of worsening myocardial ischemia. In addition, all patients should be given **sublingual or spray nitroglycerin** and instructions on how to use it.

B. **Aspirin 75 to 162 mg daily should be continued indefinitely for all patients who have had UA/NSTEMI**. Patients who have undergone PCI with a BMS should be given ASA 162 to 325 mg daily for at least 1 month after stent implantation. Patients who have undergone PCI with a drug-eluting stent (DES) should be given ASA 162 to 325 mg daily for at least 3 months after sirolimus-eluting stent implantation and at least 6 months after paclitaxel-eluting stent implantation, after which daily ASA at 75 to 162 mg should be continued indefinitely. For post-PCI patients in whom there is concern for a risk of bleeding, an initial lower dose of ASA at 75 to 162 mg/d is acceptable. For patients in whom ASA is contraindicated or not tolerated, clopidogrel 75 mg daily (preferred) or ticlopidine (if not contraindicated) should be given indefinitely.

C. **Thienopyridine therapy.** In patients with UA/NSTEMI who underwent PCI with a DES or BMS, clopidogrel, ticagrelor, or prasugrel therapy should be continued for at least 12 months and further continuation beyond 15 months may be considered. In patients in whom the risk of bleeding outweighs the expected benefits of prolonged thienopyridine therapy, early discontinuation can be considered, especially in patients who have received a BMS. UA/NSTEMI patients who were treated medically without PCI should be given clopidogrel 75 mg daily for at least 1 month, and ideally up to 1 year. Although there are currently no data proving that performing **platelet function testing** on patients on thienopyridine therapy results in improved outcomes, it is considered reasonable to do so if the results of testing would alter management.

D. **β-Blockers** should be given indefinitely to all UA/NSTEMI patients unless contraindicated. Patients recovering from UA/NSTEMI with moderate or severe LV dysfunction should be gradually titrated onto adequate β-blocker therapy. **Calcium channel blockers** (other than short-acting dihydropyridine calcium channel blockers) are recommended for ischemic symptoms when β-blockers are not successful, are contraindicated, or are not tolerated.

E. **ACE inhibitors** should be given indefinitely to all patients with UA/NSTEMI and heart failure, left ventricular ejection fraction (LVEF) < 40%, hypertension, or diabetes mellitus unless contraindicated. An ACE inhibitor is also reasonable in UA/NSTEMI patients in the absence of these conditions. **Angiotensin receptor blockers** should be given to patients who are intolerant of ACE inhibitors and have heart failure with an LVEF < 40%.

F. **Aldosterone receptor antagonists** should be given to post-UA/NSTEMI patients who do not have significant renal dysfunction (CrCl > 30 mL/min), do not have hyperkalemia (K ≤ 5 mEq/L), are already on an adequate dose of ACE inhibitor, and have heart failure or diabetes mellitus with an LVEF < 40%. In the **EPHESUS** trial, 6,642 patients post-MI (3 to 14 days) with an LVEF ≤ 40% along with either symptomatic heart failure or diabetes mellitus were randomized to oral eplerenone (starting dose of 25 mg, titrated to maximum of 50 mg/d) or placebo in addition to optimal medical therapy. In those individuals randomized to eplerenone as compared with placebo, there was a significant reduction in overall mortality (14.4% vs. 16.7%,

$p = 0.008$), cardiovascular mortality (12.3% vs. 14.6%, $p = 0.005$), and cardiovascular mortality or hospitalization for cardiovascular events (26.7% vs. 30%, $p = 0.002$) at mean follow-up of 16 months. There is an increased risk of hyperkalemia with use of this agent, particularly in those patients with abnormal renal function. In the **EPHESUS** study, there was a significant increase in the risk of serious hyperkalemia (serum potassium ≥ 6.0 mmol/L) in patients using eplerenone as compared with those in the placebo group (5.5% vs. 3.9%, $p = 0.002$). Eplerenone should not be used in those patients with severe renal insufficiency.

G. Statin therapy should be given to all patients with UA/NSTEMI, regardless of baseline low-density lipoprotein cholesterol (LDL-C) levels. LDL-C levels should be lowered to ≤ 100 mg/dL and to levels ≤ 70 mg/dL if feasible.

3-Hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (i.e., **statins**) have been shown to be integral in primary and secondary prevention of CAD. Early initiation of statin therapy has beneficial effects in patients with NSTE-ACS as well. In the **MIRACL** study involving 3,086 patients with UA/NSTEMI, treatment with atorvastatin 24 to 96 hours after presentation was associated with a decreased rate of death, nonfatal MI, cardiac arrest, or recurrent ischemia at 16 weeks (14.8% vs. 17.4%, RR = 0.84, 95% CI: 0.70 to 1.00, $p = 0.048$), primarily because of reduced recurrent symptomatic ischemia requiring hospitalization. The **PROVE IT–TIMI 22** trial demonstrated the salutary effects of aggressive lipid-lowering therapy in patients with ACS. In this study, 4,162 patients with ACS were randomized to pravastatin 40 mg daily (standard therapy) or atorvastatin 80 mg daily (intensive therapy) and followed for a mean of 24 months. There was a significant 16% reduction in the rate of death, MI, UA requiring rehospitalization, revascularization, and stroke at 2 years in those randomized to more intensive lipid-lowering therapy compared with standard lipid therapy (22.4% vs. 26.3%, $p = 0.005$). Further analysis from this trial demonstrated an early clinical benefit, which correlated with concomitant reductions in C-reactive protein levels, at 30 days with use of intensive lipid-lowering therapy. These early benefits from statin therapy are likely caused by the "pleiotropic" or nonlipid-lowering effects of statins such as their anti-inflammatory, antioxidant, and antithrombotic properties. Statins' anti-inflammatory effects are likely responsible for beneficial effects in the periprocedural MI reduction seen in patients with NSTE-ACS treated with PCI. In the **ARMYDA-ACS** study of patients with NSTE-ACS undergoing PCI, pretreatment (12 hours prior to PCI) with atorvastatin 80 mg as compared with placebo resulted in a significant reduction in death, MI, or unplanned revascularization at 30 days (5% vs. 17%, $p = 0.01$), which was driven entirely by the reduction in periprocedural MI rates (5% vs. 15%, $p = 0.04$).

CHAPTER 3

Michael P. Brunner
Venu Menon

Complications of Acute Myocardial Infarction

I. INTRODUCTION. **In-hospital mortality after acute myocardial infarction (MI) is primarily caused by circulatory failure from severe left ventricular (LV) dysfunction and/or other acute complications of MI.** These complications can be broadly classified as **mechanical, arrhythmic, embolic, and inflammatory (e.g., pericarditis)**.

II. MECHANICAL COMPLICATIONS. Mechanical complications of acute MI include ventricular septal rupture (VSR), acute mitral regurgitation (MR), ventricular free wall rupture, ventricular pseudoaneurysm, and ventricular aneurysm.

A. Ventricular septal rupture

1. **Clinical presentation.** VSR occurred in 1% to 2% of patients after acute MI in the prethrombolytic era and accounted for 5% of the periinfarction mortality. The incidence has dramatically decreased in the postthrombolytic era. In the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries 1 (GUSTO-1) trial, the incidence of VSR was approximately 0.2%, occurring with equal frequency in anterior and non-anterior locations. VSR is more likely to occur in patients who are **older, female, and hypertensive and have no prior history of smoking.** It commonly occurs in the setting of a **first MI, in the background of delayed or absent reperfusion therapy.** Angiography usually reveals an **absence of collateral circulation to the infarct zone**. VSR may develop as early as 24 hours after MI but is usually seen 2 to 5 days after MI. Fibrinolytic therapy is not associated with increased risk of VSR but may accelerate rupture in vulnerable subjects, accounting for the "early hazard" observed with treatment over placebo in randomized clinical trials.
   a. **Signs and symptoms.** Patients with post-MI VSR may appear relatively comfortable early in the disease course. Recurrence of angina, pulmonary edema, hypotension, and shock may develop abruptly later in the course. Alternatively, precipitous onset of hemodynamic compromise characterized by hypotension, biventricular failure, and a new murmur may be the initial manifestation.
   b. **Physical findings.** The diagnosis should be suspected when a new **pansystolic murmur** develops, especially in the setting of worsening hemodynamic profile and biventricular failure. For this reason, it is important that **all patients with MI have a well-documented cardiac examination** at presentation and frequent evaluations thereafter. This assumes critical importance as systems struggle to achieve optimal door-to-balloon times.
      (1) The murmur is usually best heard at the **lower left sternal border**; it is accompanied by a **thrill in 50% of the cases**. In patients with a large

TABLE 3.1 Differential Diagnosis of a New Systolic Murmur after Acute Myocardial Infarction

Differentiating features	Ventricular septal rupture	Acute mitral regurgitation
Location of MI	Anterior = nonanterior	Inferoposterior > anterior
Location of murmur	Lower left sternal border	Cardiac apex
Intensity	Loud	Variable; may be faint
Thrill	50% of patients	Rare
RV failure	More likely	Less likely
Pulmonary edema	Less likely	More likely
V waves in PCWP	Present or absent	Almost always present
V waves in PA tracing	Absent	Present
O_2 step-up in PA	Almost always present	Present or absent

MI, myocardial infarction; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; RV, right ventricular.

VSR and severe heart failure or cardiogenic shock, the murmur may be of low intensity or inaudible, but **the absence of a murmur does not rule out VSR**.

(2) Several features differentiate the murmur of VSR from that of acute MR (Table 3.1). The murmur may radiate to the base and the apex of the heart. A third heart sound (S_3), loud P_2, and signs of tricuspid regurgitation may be present.

2. **Histopathology.** The defect usually occurs at the myocardial infarct border zone, located in the **apical septum with anterior MI** and in the **basal posterior septum with inferior MI**. A VSR almost always occurs in the setting of a transmural MI. The defect may not always be a single large defect; a meshwork of serpiginous channels can be identified in 30% to 40% of patients. Multiple fenestrations are especially common with inferior MIs.
3. **Diagnostic testing**
   a. **An electrocardiogram** (ECG) may show atrioventricular (AV) node or infranodal conduction abnormalities in approximately 40% of patients.
   b. **Echocardiography**
      (1) **Transthoracic echocardiography is the test of choice** for the diagnosis of VSR. It is important for the clinician to interrogate the area of interest with color Doppler ultrasound. Lowering the Nyquist limit will enable definition and help define the size of the defect. The echocardiogram will also provide insight into the feasibility of utilizing temporizing percutaneous closure devices in this setting.
         (a) **Basal VSR** is best visualized in the parasternal long axis with medial angulation, the apical long axis, and the subcostal long axis.
         (b) **Apical VSR** is best visualized in the apical four-chamber view.
      (2) In some cases, **transesophageal echocardiography** may help in determining the extent of the defect and assessing suitability for potential percutaneous closure.
      (3) Echocardiography may help determine the size of the defect and the magnitude of the left-to-right shunt by comparing flow across the pulmonary valve with flow across the aortic valve.

(4) An assessment of right ventricular (RV) and LV function is key to prognostication and management as they remain important determinants of mortality.

c. **Right heart catheterization.** Pulmonary artery (PA) catheterization with oximetry measurement can help diagnose VSR by demonstrating an oxygen saturation step-up in the RV and PA. The **location of the increase is significant** because there have been case reports of enhanced oxygen saturation in the peripheral PA due to acute MR. Diagnosis involves fluoroscopically guided measurement of the oxygen saturation in the superior and inferior venae cavae; high, mid, and low right atrium (RA); base, mid, and apical levels of the RV; and the PA.

(1) Normal oxygen saturations for these chambers are 64% to 66% in the superior vena cava (SVC), 69% to 71% in the inferior vena cava (IVC), 64% to 67% in the RA, 64% to 67% in the RV, and 64% to 67% in the PA.

(2) An oxygen step-up at the level of the RV is characteristically seen with VSR. A left-to-right shunt across the ventricular septum typically results in a **5% or greater** increase in oxygen saturation between the RA and the RV or PA.

(3) **Shunt fraction is calculated as follows:**

$$Q_p/Q_s = (Sa{O_2} - Mv{O_2})/(Pv{O_2} - Pa{O_2})$$

In this equation, Q_p is pulmonary flow; Q_s is systemic flow; $Sa{O_2}$ is peripheral arterial oxygen saturation; $Mv{O_2}$ is mixed venous oxygen saturation; $Pv{O_2}$ is pulmonary venous oxygen saturation; and $Pa{O_2}$ is pulmonary arterial oxygen saturation. $Mv{O_2}$ is calculated by multiplying the SVC oxygen saturation by three, adding the IVC oxygen saturation, and then dividing the sum by four. $Pv{O_2}$ is generally assumed to be equal to the peripheral oxygen saturation. **Qp/Qs ≥ 2 suggests the presence of a considerable shunt. In the acute MI setting, any VSR should be considered for urgent surgical repair, regardless of the shunt fraction**.

(4) For a patient with an intracardiac shunt, **cardiac output measured by means of the thermodilution technique is inaccurate; the Fick method should be used**. The key to measurement of accurate systemic flow in the presence of a shunt is that the oxygen content measured in the PA will be abnormally elevated and must be measured in the chamber immediately **proximal** to the shunt (i.e., the RA or the SVC and IVC in the case of VSR). The Fick equation is normally calculated as follows:

$$\text{Cardiac output} = O_2 \text{ consumption}/([Sa{O_2} - Pa{O_2}] \times Hgb \times 1.34 \times 10)$$

d. **Left heart catheterization.** Ventriculography performed after angiography or percutaneous intervention (PCI) may reveal VSR if the suspicion is high. Visualization is best in the left anterior oblique projection with cranial angulation.

e. **Cardiac MRI and CT** are additional imaging modalities that can be utilized. However, the studies are more difficult to perform in hemodynamically unstable patients and do not play a significant role in this setting.

4. **Therapy**

a. **Priority of therapy.** Urgent surgical closure is the treatment of choice (AHA/ACC class I recommendation), especially when the patient's condition is stable because hemodynamic deterioration in this setting is unpredictable. Although initial reports suggested that delaying surgery to allow healing of friable tissue improved surgical mortality, it was likely that lower mortality

was simply a result of selection bias. The mortality rate for patients with VSR treated medically is 24% at 72 hours and 75% at 3 weeks.

b. Vasodilators can decrease left-to-right shunt and increase systemic flow by means of reducing systemic vascular resistance (SVR); however, a greater decrease in pulmonary vascular resistance may actually increase shunting. The vasodilator of choice is **intravenous nitroprusside**, which is started at 0.5 to 0.8 μg/kg/min and titrated to a mean arterial pressure (MAP) of 70 to 80 mm Hg.

c. An **intraaortic balloon pump (IABP)** should be inserted as early as possible as a bridge to a surgical procedure, unless there is marked aortic regurgitation. IABP counterpulsation decreases SVR, decreases shunt fraction, increases coronary perfusion, and maintains blood pressure. After insertion of an IABP, vasodilators can be tailored with hemodynamic monitoring.

d. Surgical therapy

(1) Cardiogenic shock and multisystem failure are associated with high surgical mortality, further supporting earlier operations on these patients before complications develop. Mortality in patients with cardiogenic shock and VSR was 81% in the SHOCK (SHould we emergently revascularize Occluded coronaries for Cardiogenic shocK?) trial registry (1).

(2) Surgical mortality is high among patients with **basal septal rupture associated with inferior MI** (70% compared with 30% in patients with anterior infarcts) because of the greater technical difficulty and the need for concomitant mitral valve repair in these patients, who often have coexisting MR. RV dysfunction due to infarction and/or pressure and volume overload further increases the risk profile of these subjects.

e. Percutaneous therapy. Although surgical closure remains the treatment of choice for VSR, emerging data suggest that **percutaneous closure** may be a viable treatment for high-risk surgical patients and patients in whom surgical closure has failed. In a series of 29 patients treated with percutaneous VSR closure at a median time of 1 day after MI, mortality at 30 days in patients treated with successful device placement was 36% and 86% without and with cardiogenic shock, respectively. At a median follow-up of 730 days, mortality was 36% and 93%, respectively. In our institution, a percutaneous approach is utilized for temporary palliation and as a bridge to surgical repair only in patients considered too high risk to undergo surgery.

B. Acute MR. The incidence of acute MR after MI was 13% to 39% in large registries such as GUSTO-1 and SHOCK. Fibrinolytic agents decrease the overall incidence, but rupture may occur earlier in the post-MI period. MR, even if clinically silent, is a predictor of poor prognosis in MI. Multiple mechanisms may account for acute MR. These include dilation of the mitral valve annulus as a result of LV dilation; papillary muscle dysfunction with a concomitant ischemic regional wall motion abnormality near the insertion of the posterior papillary muscle; and partial or complete rupture of the chordae or papillary muscle. Severe MR caused by papillary muscle rupture is a life-threatening complication of acute MI. Historical reports indicate that papillary muscle rupture occurs between days 2 and 7. However, the SHOCK registry revealed a median time to papillary muscle rupture of 13 hours. Acute severe MR accounted for 7% of the cases of cardiogenic shock and 5% of mortality after acute MI in the SHOCK registry.

1. Clinical presentation

a. Signs and symptoms. These are variable and depend on the anatomy of the papillary muscle involved, the mechanism of valvular dysfunction, and the extent of injury. Complete transection of the papillary muscle is rare and usually results in immediate cardiogenic shock and death. Patients with partial or complete rupture of one or more heads of the papillary muscle lose

significant leaflet support. The resultant torrential MR can result in pulmonary edema and severe respiratory distress.

b. **Physical findings.** A new **pansystolic murmur that is audible at the cardiac apex with radiation to the axilla or the base of the heart suggests acute MR**. In posterior papillary muscle rupture, the murmur radiates to the left sternal border and may be confused with the murmur of VSR or aortic stenosis. The intensity of the murmur does not predict the severity of the MR. The **murmur may often be quiet, soft, or absent** in patients with poor cardiac output or in persons with elevated left atrial pressure due to the rapid equilibration of pressures. Resting tachycardia and mechanical ventilation can also make murmur recognition challenging.

2. **Pathophysiology.** Papillary muscle rupture is **more common with an inferior MI** because the posteromedial papillary muscle receives blood supply from the posterior descending artery, whereas the anterolateral papillary muscle has dual blood supply from the left anterior descending (LAD) and circumflex arteries. Papillary muscle rupture is more likely to occur in patients with a **first MI**, and in many patients the **infarct size may be relatively small. The discordance between the degree of hemodynamic instability and the extent of myocardium in jeopardy is often a clue to the underlying condition**.

3. **Diagnostic testing**
   a. An **ECG** usually shows evidence of recent inferior or posterior MI.
   b. A **chest radiograph** may demonstrate pulmonary edema. In some patients, focal pulmonary edema may be seen in the right upper lobe because of flow directed at the right pulmonary veins.
   c. **Transthoracic echocardiography** with Doppler and color flow imaging is the diagnostic modality of choice.
      (1) The **mitral valve leaflet is usually flail** with severe MR.
      (2) Color Doppler imaging is useful in differentiating papillary muscle rupture with severe MR from VSR after MI.
   d. **Transesophageal echocardiography. Transthoracic echo may underestimate the degree of acute MR**. Rapid equalization of pressure, resting tachycardia, and poor acoustic windows may contribute to this finding. An eccentric jet in this setting should lead to the performance of **transesophageal echocardiography** to quantify the severity and elucidate the mechanism of MR.
   e. **PA catheterization.** Hemodynamic monitoring with a PA catheter may reveal large V waves in the pulmonary capillary wedge pressure (PCWP) tracing. However, patients with VSR may also have large V waves because of increased pulmonary venous return in a normal-sized and normally compliant left atrium. Among patients with severe MR and reflected V waves in the PA tracing, **oxygen saturation in the PA may be higher** than that in the RA, complicating differentiation from VSR. There are two methods for differentiating MR from VSR:
      (1) Prominent V waves in the PA tracing before the incisura are almost always associated with acute severe MR (Fig. 3.1).
      (2) Blood for oximetry is obtained with fluoroscopy to ensure sampling from the main PA rather than distal branches.

4. **Therapy**
   a. **Priority of therapy.** Papillary muscle rupture should be identified early. Patients should receive **aggressive medical therapy** and consideration for **emergent surgical repair**.
   b. **Vasodilator therapy** is beneficial in the treatment of patients with acute MR. **Intravenous nitroprusside** decreases SVR, reduces regurgitant fraction, and increases stroke volume and cardiac output. Nitroprusside is started at 0.5 to 0.8 μg/kg/min and is titrated to an MAP of 70 to 80 mm Hg.

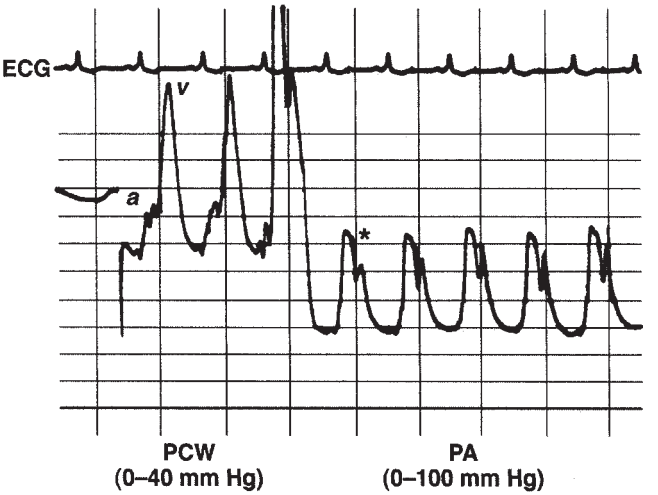

FIGURE 3.1 Giant V waves on the pulmonary capillary wedge (PCW) tracing can be transmitted to the pulmonary artery (PA) pressure, producing a notch (*asterisk*) on the PA downslope. (Adapted from Kern M. *The Cardiac Catheterization Handbook.* 2nd ed. St. Louis, MO: Mosby-Year Book; 1991.)

c. **Intraaortic balloon pump.** Vasodilator therapy is contraindicated in patients with significant **hypotension** and an IABP should be inserted promptly. An IABP decreases LV afterload, improves coronary perfusion, and increases forward cardiac output. Patients with hypotension can often be given vasodilators after insertion of an IABP to improve hemodynamic values.

d. **Percutaneous therapy.** Improvement in hemodynamic values and reduction in MR has been reported after PCI in patients with severe MR caused by papillary muscle ischemia rather than rupture. However, this is a relatively rare clinical presentation. **PCIs have no role in true papillary muscle rupture**.

e. **Surgical therapy should be considered immediately for patients with papillary muscle rupture.**

(1) The prognosis is very poor among patients treated medically. Even though perioperative mortality (20% to 25%) is higher than that for elective surgical treatment, surgical therapy should be considered for every patient.

(2) **Coronary angiography** should be performed before surgical correction, because revascularization is associated with improved short- and long-term mortality.

C. **Ventricular free wall rupture**

1. **Clinical presentation.** The incidence of ventricular free wall rupture after MI in the reperfusion era is < 1%. However, ventricular free wall rupture accounts for approximately **10% of mortality after MI**. In the SHOCK registry, in-hospital mortality associated with ventricular rupture was > 60%. Rupture occurs in the

first 5 days in 50% of patients and within 2 weeks in 90% of patients. Ventricular free wall rupture occurs in the setting of a transmural MI. Risk factors include advanced age, female sex, first MI, and poor coronary collateral vessels.

a. Signs and symptoms

(1) Acute course. With acute rupture, patients develop tamponade, electromechanical dissociation, and sudden death. Sudden onset of chest pain with straining or coughing may suggest the onset of myocardial rupture.

(2) Subacute course. Some patients may have a contained rupture and present subacutely with pain suggestive of pericarditis, nausea, and hypotension. In a large retrospective analysis of post-MI patients, 2.6% of patients were found to have sustained subacute ventricular free wall rupture. Immediate bedside echocardiography may reveal localized pericardial effusion or pseudoaneurysm.

b. Physical findings. Jugular venous distention, pulsus paradoxus, diminished heart sounds, and a pericardial rub suggest subacute rupture. New to-and-fro murmurs may be heard in patients with subacute rupture or pseudoaneurysm.

2. Pathophysiology

a. Ventricular free wall rupture constitutes part of the "early hazard" of thrombolytic therapy. Mortality among patients who receive thrombolytic agents is higher for the first 24 hours and is partially attributable to ventricular rupture. Nevertheless, the overall incidence of ventricular free wall rupture is not greater in patients treated with thrombolytics. The incidence of ventricular free wall rupture is lower in patients treated with primary angioplasty compared with thrombolytics. Rupture most commonly occurs at the anterior or lateral wall, although any wall may be involved.

b. There are **three distinct types of ventricular free wall rupture** (Fig. 3.2):

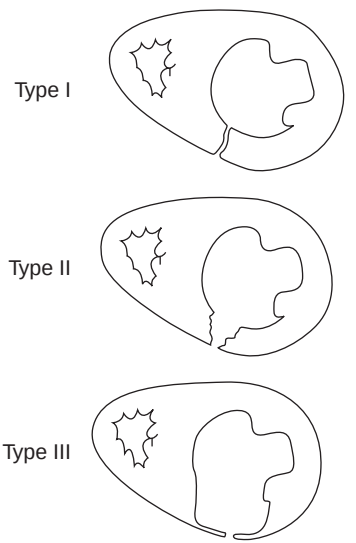

FIGURE 3.2 Morphologic classification of ventricular free wall rupture. (Reprinted with permission from Becker AE, van Mantgem JP. Cardiac tamponade. A study of 50 hearts. *Eur J Cardiol.* 1975;3:349-358.)

(1) **Type I** generally occurs within the first 24 hours and is a slitlike full-thickness rupture characterized by abrupt onset of symptoms (this rupture type increases with thrombolytics).
(2) **Type II** occurs as a result of erosion of the myocardium at the site of infarction. The rupture progresses more slowly and symptoms may be subacute.
(3) **Type III** occurs late and is characterized by expansion of the infarct zone with marked wall thinning and then rupture through the subsequent aneurysmal segment. It has been postulated that type III rupture occurs as a result of dynamic left ventricular outflow tract (LVOT) obstruction and the resultant increased wall stress. Type III rupture occurs less frequently in patients treated with thrombolytics.

3. **Diagnostic testing.** There may not be time for diagnostic testing in the treatment of patients with acute ventricular free wall rupture.
   a. In addition to evidence for new MI, an **ECG** may show junctional or idioventricular rhythm, low-voltage complexes, and tall precordial T waves. A large proportion of patients have transient bradycardia immediately preceding rupture.
   b. **Transthoracic echocardiography** reveals findings of **cardiac tamponade** in patients with a subacute course: RA and RV diastolic collapse, dilated IVC (i.e., IVC plethora), and marked respiratory variation in mitral (> 25%) and tricuspid (> 40%) inflow. Visualization of ventricular free wall rupture may be improved with echocardiographic contrast agents.
   c. **Cardiac catheterization.** Hemodynamic evaluation with a PA catheter may reveal **equalization of the RA pressure, RV diastolic pressure, PA diastolic pressure, and PCWP** consistent with pericardial tamponade. During left heart catheterization, analysis of the arterial waveform may reveal significant **respiratory variations in the systolic blood pressure (pulsus paradoxus)**. Ventriculography performed in the right anterior or left anterior oblique orientation may allow visualization of the rupture.
   d. **Cardiac MRI and CT** can be utilized in hemodynamically stable patients but are usually not available for critical decision making.
4. **Therapy.** Reperfusion therapy has reduced the overall incidence of cardiac rupture.
   a. **Priority of therapy.** The goal is to rapidly identify the problem and perform emergency surgical treatment.
   b. **Medical therapy** has little role in the treatment of these patients, except for aggressive supportive care in anticipation of surgical correction.
   c. **Percutaneous therapy**
      (1) **In the setting of hemodynamic extremis, immediate pericardiocentesis** should be performed in patients with tamponade as soon as the diagnosis is made and while arrangements are being made for transport to the operating room.
      (2) If the index of suspicion is high and the patient's condition is unstable, pericardiocentesis should be attempted without waiting for diagnostic test results.
      (3) An indwelling catheter should be clamped and left in the pericardial cavity and connected to a drainage bag during transfer to the operating room so that continued decompression of the pericardial cavity with recurrent hemodynamic compromise can be achieved.
   d. **Surgical therapy.** Emergency thoracotomy with surgical repair is the definitive therapy and is the **only chance for survival among patients with acute ventricular free wall rupture**.

D. Ventricular pseudoaneurysm (i.e., contained rupture)

1. **Clinical presentation.** Ventricular pseudoaneurysm is **more likely to occur with inferior MI than with anterior MI** (2).
   a. **Signs and symptoms.** Pseudoaneurysms may remain clinically silent and be discovered during routine investigation. However, patients may present with chest pain, dyspnea, recurrent tachyarrhythmia, and sudden cardiac death.
   b. **Physical findings.** Systolic, diastolic, or to-and-fro murmurs related to flow of blood across the narrow neck of the pseudoaneurysm during systole and diastole may be appreciated.
2. **Pathophysiology.** Ventricular pseudoaneurysm is caused by contained rupture of the LV free wall.
   a. The **outer walls of a true ventricular aneurysm are formed by infarcted myocardium and scar**, whereas the **outer walls of a pseudoaneurysm are formed by the pericardium and mural thrombus**. A pseudoaneurysm may remain small or undergo progressive enlargement.
   b. Ventricular pseudoaneurysms communicate with the body of the ventricle through a **narrow neck, the diameter of which is < 50% of the diameter of the fundus**.
3. **Diagnostic testing**
   a. A **chest radiograph** may show cardiomegaly with an abnormal bulge on the cardiac border.
   b. An **ECG** may demonstrate persistent ST-segment elevation, as with true aneurysms.
   c. **Ventriculography is the most reliable method of diagnosis**.
   d. **Echocardiography, cardiac MRI, and cardiac CT** may be utilized in evaluation as well. Echocardiographic contrast agents may increase the diagnostic accuracy.
4. **Therapy.** Spontaneous rupture may occur without warning in approximately one-third of patients with a pseudoaneurysm. **Surgical resection is recommended for patients with or without symptoms, regardless of the size of the pseudoaneurysm, to minimize the risk of death**.

E. Ventricular aneurysm

1. **Clinical presentation.** The incidence of ventricular aneurysm after MI in the reperfusion era is approximately 15% and occurs **more commonly with anterior MI than with inferior or posterior MI**.
   a. **Signs and symptoms**
      (1) **Acute aneurysm.** Acute development of a large ventricular aneurysm can result in severe LV dysfunction and cardiogenic shock. Patients with an acute MI that involves the apex of the LV, particularly those with transmural anteroapical infarcts, are at greatest risk. Acute aneurysms expand during systole. This expansion wastes contractile energy generated by normal myocardium and puts the entire ventricle at a mechanical disadvantage.
      (2) **Chronic aneurysms** persist > 6 weeks after MI, are less compliant than acute aneurysms, and rarely expand during systole. Patients with chronic aneurysms may experience heart failure, ventricular arrhythmias, mural thrombus, and systemic embolism, but they frequently have no symptoms.
   b. **Physical findings.** A dyskinetic segment of the ventricle may be apparent during inspection or may be felt during palpation. The apical impulse may be displaced to the left of the midclavicular line due to cardiac enlargement. An S_3 or S_4 gallop may be appreciated due to LV dilation and stiffening. A systolic murmur of MR may occur due to changes in LV geometry.
2. **Pathophysiology.** Infarct expansion and progressive LV dilation are consequences of absent or ineffective coronary reperfusion. The aneurysmal segment initially consists of necrotic tissue and is later replaced by fibrous scar tissue.

3. **Diagnostic testing**
   a. **ECG**
      (1) **Acute aneurysm.** The ECG reveals evidence of ST-segment elevation MI, which may persist despite evidence of reperfusion.
      (2) **Chronic aneurysm.** ST-segment elevation that persists > 6 weeks occurs in patients with chronic ventricular aneurysms.
   b. **Chest radiography** may reveal a localized bulge in the cardiac silhouette.
   c. **Transthoracic echocardiography** is the diagnostic **test of choice** and accurately depicts the aneurysmal segment. It may also reveal the presence of a mural thrombus. Echocardiography is useful in differentiating a true aneurysm from a pseudoaneurysm. True aneurysms have a wide neck, whereas pseudoaneurysms have a narrow neck in relation to the diameter of the aneurysm.
   d. Cardiac **MRI and CT** may also be utilized to characterize ventricular aneurysm.
4. **Therapy**
   a. **Medical therapy**
      (1) **Acute aneurysm.** LV failure caused by acute aneurysm is managed with **intravenous vasodilators** and **IABP** therapy. **Angiotensin-converting enzyme (ACE) inhibitors** have been shown to reduce infarct expansion and progressive LV remodeling. Because infarct expansion starts early, ACE inhibitors should be initiated within the first 24 hours of the onset of acute MI if blood pressure allows.
      (2) **Chronic aneurysm.** Heart failure associated with chronic aneurysm formation is managed with afterload reduction, namely with ACE inhibitors.
      (3) **Anticoagulation**
         (a) Anticoagulation with **warfarin sodium** should be prescribed (AHA/ACC class I indication) to patients found to have a LV mural thrombus or embolic phenomenon. Patients are initially treated with intravenous heparin with a target partial thromboplastin time (PTT) of 50 to 65 seconds. Warfarin is started simultaneously. Patients should be treated with warfarin to a target international normalized ratio (INR) of 2 to 3 for at least 3 months and then indefinitely if the risk of bleeding is not excessive. Novel oral anticoagulants such as dabigatran etexilate and rivaroxaban have not been approved for this indication at this time.
         (b) It is reasonable (AHA/ACC class IIa indication) to prescribe prophylactic anticoagulation to patients with LV dysfunction and extensive regional wall motion abnormalities that do not have a mural thrombus.
         (c) Patients with MI requiring dual antiplatelet therapy because of PCI need to have the benefits of anticoagulation weighed against an **increase in bleeding risk with triple therapy**.
   b. **Surgical therapy.** Patients with refractory heart failure and/or refractory ventricular arrhythmias should be considered for aneurysmectomy. Surgical resection may be followed by conventional closure or newer techniques (e.g., inverted T closure and endocardial patch) to maintain LV geometry.

F. **LV failure and cardiogenic shock.** Please refer to Chapter 4 for further discussion.

G. **RV failure.** Mild RV dysfunction is common after **MI of the inferior or inferoposterior wall**; however, hemodynamically significant RV impairment occurs in only 10% of patients. The **proximal right coronary artery** (RCA) is commonly involved. Extensive, irreversible RV damage is unusual because the RV has lower oxygen requirements due to its smaller muscle mass, is perfused during systole and

diastole, and often receives extensive left to right collateral blood flow. Most patients with RV infarction who survive the acute phase spontaneously improve after 48 to 72 hours.

1. **Clinical presentation**
   a. **Signs and symptoms.** The triad of **hypotension, jugular venous distention, and clear lung fields** is highly specific (but has poor sensitivity) for RV infarction. Patients with severe RV failure have symptoms of a low cardiac output state, including diaphoresis; cool, clammy extremities; and altered mental status. Patients often are hypotensive and oliguric. The use of **nitrates or β-blockers during routine MI treatment may precipitate profound hypotension** and provide the first clue of RV involvement. Table 3.2 lists causes of hypotension among patients with inferior wall MI.
   b. **Physical findings.** Patients with RV failure without concomitant LV failure may have elevated jugular venous pressure (JVP) and a RV S_3 with clear lungs. The combination of JVP > 8 cm H_2O and **Kussmaul's sign** (i.e., failure of JVP to decrease with inspiration) is sensitive and specific for severe RV failure. Elevated right-sided pressures can occasionally result in **right-to-left shunting** through a patent foramen ovale. This should be considered in patients with RV infarction and hypoxia. Table 3.3 lists the clinical findings associated with an RV infarction.
2. **Pathophysiology.** RV involvement depends on the location of the RCA occlusion. Marked dysfunction occurs only if occlusion is proximal to the acute marginal branch. The degree of RV involvement also depends on the presence of left to right collateralization and the extent of diastolic reverse perfusion through the thebesian veins.
3. **Diagnostic testing**
   a. An **ECG** usually shows **inferior ST-segment elevation**. ST-segment elevation in **V_4R** in the setting of suspected RV infarction has a positive predictive value of 80%. RV infarction is also suggested by ST-segment elevation that is greater in lead III than lead II. ST-segment elevation exceeding 1 mm may be seen in V_1 and occasionally in V_2 and V_3 (Fig. 3.3).
   b. A **chest radiograph** is usually normal and there is no evidence of pulmonary congestion.
   c. **Transthoracic echocardiography** is the diagnostic **study of choice** for RV infarction. It may demonstrate RV dilation and severe RV dysfunction and usually shows LV inferior wall dysfunction. It is also useful in

TABLE 3.2 Causes of Hypotension in Patients Presenting with Inferior Myocardial Infarction

Right ventricular infarction
Left ventricular failure
Bradyarrhythmia
Acute severe mitral regurgitation
Ventricular septal rupture
Bezold-Jarisch reflex

TABLE 3.3 Clinical Findings Associated with Right Ventricular Infarction

Hypotension
Elevated jugular venous pressure
Kussmaul's sign
Abnormal jugular venous pressure pattern (y ≥ x descent)
Tricuspid regurgitation
Right-sided S_3 and S_4
Pulsus paradoxus
High-grade atrioventricular block

differentiating RV infarction from other syndromes that can mimic it, such as cardiac tamponade.

d. Pulmonary artery catheterization. Hemodynamic monitoring with a PA catheter usually reveals **high RA pressures with low PCWP**. Acute RV failure results in underfilling of the LV and a low cardiac output state. The PCWP is usually low unless concomitant, severe LV dysfunction is present. In some patients, RV dilation can cause decreased LV performance resulting from ventricular interdependence. As the RV dilates, the septum flattens or bows into the LV and restricts ventricular filling. RA pressure > 10 mm Hg and RA pressure to PCWP ratio ≥ 0.8 strongly suggests RV infarction.

4. Therapy

a. Medical therapy

(1) Fluid administration. Management of RV infarction involves volume loading to increase preload and cardiac output. Some patients may require several liters in 1 hour. **Hemodynamic monitoring is crucial** because overzealous fluid administration in a patient with severe RV dilation can further decrease LV preload and cardiac output. Excessive fluid administration can cause the ventricular septum to shift toward the LV and impede LV filling. The target central venous pressure is approximately 15 mm Hg.

(2) Inotropes. When volume loading fails to increase cardiac output, the use of inotropes is indicated. Administration of **dobutamine** increases cardiac index and RV ejection fraction and is superior to afterload reduction with nitroprusside.

b. Percutaneous therapy

(1) Patients who undergo successful **reperfusion** of the RV have improved RV function and decreased 30-day mortality rates.

(2) AV sequential pacing may markedly improve the condition of a patient with RV infarction and bradyarrhythmia or loss of sinus rhythm. **A longer AV delay of approximately 200 milliseconds and a heart rate of 80 to 90 beats per minute are usually optimal for these patients.**

(3) An IABP may be beneficial, especially in cases of concomitant LV dysfunction.

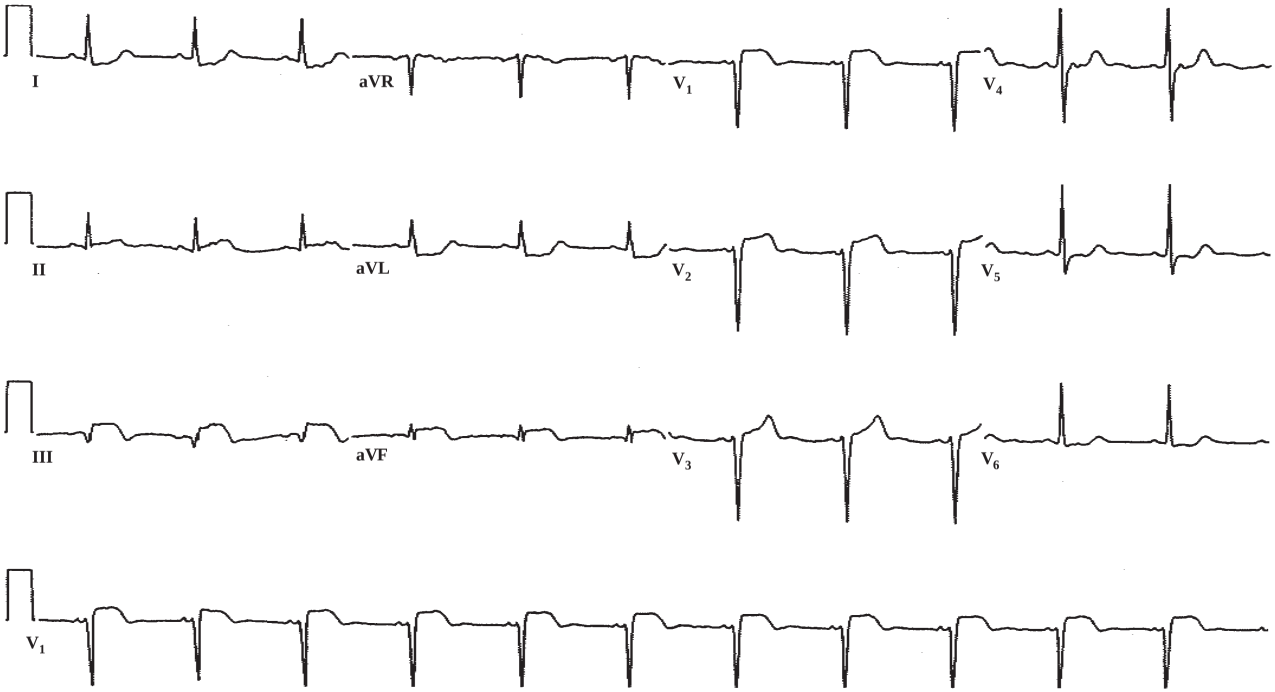

FIGURE 3.3 Electrocardiogram demonstrating acute inferior myocardial infarction with right ventricular involvement.

c. **Surgical therapy**
   (1) **Pericardiectomy** may be considered in the care of patients with refractory shock as it reverses the septal impingement on LV filling.
   (2) An **RV assist device** is indicated in the care of patients who remain in cardiogenic shock despite the foregoing measures.

H. Dynamic LVOT obstruction. Dynamic LVOT obstruction is an **uncommon complication** of acute anterior MI. Although this complication has been cited only in case reports, it may be an underappreciated and underreported complication.

1. **Clinical presentation**
   a. **Signs and symptoms.** Patients may have respiratory distress, diaphoresis, and cool, clammy extremities in addition to the typical signs and symptoms of acute MI. Patients with severe obstruction may appear to be in cardiogenic shock, with severe orthopnea, dyspnea, and oliguria in addition to altered mental status from cerebral hypoperfusion.
   b. **Physical findings** frequently include a new systolic ejection murmur heard best at the left upper sternal border with radiation to the neck. A new systolic murmur can be heard at the apex with radiation to the axilla, as a result of systolic anterior motion (SAM) of the mitral leaflet. An S_3 gallop, pulmonary rales, hypotension, and tachycardia may also occur.
2. **Pathophysiology.** The dynamic LVOT obstruction that may occur as a complication of acute anterior MI is related to compensatory hyperkinesis of the basal and mid segments of the LV. The increased contractile force of these regions decreases the cross-sectional area of the LVOT. The resultant increase in velocity of blood through the outflow tract can produce decreased pressure below the mitral valve and cause anterior mitral valve leaflet displacement toward the septum (i.e., Venturi effect). This results in further outflow tract obstruction and MR. It has been postulated that this complication can play a role in ventricular free wall rupture. LVOT obstruction leads to increased end-systolic intraventricular pressure, which leads to increased stress of the weakened, necrotic infarcted zone.
3. **Diagnostic testing. Transthoracic echocardiography** is the diagnostic test of choice and helps evaluate the hyperkinetic segments, the LVOT obstruction, and the presence of systolic SAM of the mitral leaflet.
4. **Medical therapy** is focused on decreasing myocardial contractility and heart rate while expanding intravascular volume and increasing afterload modestly.
   a. **β-Blockers** should be added slowly and with careful monitoring of the heart rate, blood pressure, and cardiac output.
   b. **Intravenous hydration** should be initiated with several small (250 mL) boluses of normal saline to increase preload and decrease LVOT obstruction and SAM. The patient's hemodynamic and respiratory status should be monitored closely during this therapeutic intervention.

III. ARRHYTHMIC COMPLICATIONS. Arrhythmias are a common complication after acute MI and are associated with significant mortality. Please refer to Chapters 21 through 25 and 41 for further discussion.

IV. EMBOLIC COMPLICATIONS. The contemporary incidence of LV mural thrombus after acute MI is approximately 5% and the incidence of systemic embolism in patients with LV mural thrombus is approximately 13%. The incidence of mural thrombus in patients with a **large anterior wall MI** is approximately 10%. Other factors associated with LV mural thrombus include **decreased LV ejection fraction, wall motion abnormalities, and LV aneurysm**.

A. **Clinical presentation**
   1. **Signs and symptoms.** The most common clinical presentation of an embolic complication is stroke, although patients may have limb ischemia, renal infarction, and intestinal ischemia. Most episodes of systemic embolization occur in the first 2 weeks after acute MI.
   2. **Physical findings.** The physical findings depend on the site of embolism.
      a. Patients with stroke present with neurologic deficits.
      b. Embolism to the peripheral circulation results in limb ischemia and cold, pulseless, and painful extremities.
      c. Renal infarctions may cause hematuria and flank pain.
      d. Mesenteric ischemia causes abdominal pain and bloody diarrhea.
   3. **Diagnostic testing**
      a. **Transthoracic echocardiography** is the initial diagnostic test of choice to evaluate for LV mural thrombus. Echocardiographic contrast agents may increase the diagnostic accuracy.
      b. **Cardiac MRI** has similar specificity but may be more sensitive than echocardiography in the detection of an LV mural thrombus.

B. **Therapy** with anticoagulation is outlined above in the management of ventricular aneurysm.

V. INFLAMMATORY COMPLICATIONS

A. **Early pericarditis.** The incidence of early pericarditis after acute MI is approximately 10%. The inflammation usually develops 24 to 96 hours after MI.
   1. **Clinical presentation.** Early pericarditis occurs in patients with transmural MI. A transient pericardial friction rub may be audible in some patients before symptoms become prominent.
      a. **Signs and symptoms**
         (1) Patients report progressive, severe chest pain that lasts for hours. The **pain is postural**: worse when the patient is supine and alleviated if the patient sits up and leans forward. The pain is usually pleuritic in nature and is worsened with deep inspiration, coughing, and swallowing.
         (2) **Radiation of pain to the trapezius ridge** is nearly pathognomonic for acute pericarditis and does not occur in patients with ischemic pain. The pain may also radiate to the neck and less frequently to the arm or back.
      b. **Physical findings.** The presence of a pericardial friction rub is pathognomonic for acute pericarditis; however, it can be evanescent.
         (1) The rub is best heard at the left lower sternal edge with the diaphragm of the stethoscope.
         (2) The rub has three components: one component each in atrial systole, ventricular systole, and ventricular diastole. In about 30% of patients, the rub is biphasic, and in 10% it is uniphasic.
         (3) The development of pericardial effusion may cause fluctuations in the intensity of the rub, although the rub may still be heard despite substantial pericardial effusion.
   2. **Etiology and pathophysiology.** Pericarditis typically results from an area of localized pericardial inflammation overlying the infarcted myocardium. The inflammation is fibrinous in nature. The development of an evanescent pericardial rub correlates with a larger infarct and hemodynamic derangements.

3. **Diagnostic testing**
   a. An **ECG** is the most useful test in the diagnosis of pericarditis; however, evolving electrocardiographic changes may make the diagnosis difficult for patients who have had MI. Unlike ischemia, in which the changes are limited to a particular territory, pericarditis produces generalized electrocardiographic changes.
      (1) The ST-segment elevation seen with pericarditis is a concave upward or saddle-shaped curve.
      (2) In pericarditis, T waves become inverted after the ST segment becomes isoelectric, whereas in acute MI, T waves may become inverted when the ST segment is still elevated.
      (3) Four phases of electrocardiographic abnormality have been described in association with pericarditis (Table 3.4).
   b. **Chest radiography** is of limited value in the diagnosis of pericarditis.
   c. **Echocardiography** may reveal pericardial effusion, which strongly suggests pericarditis, although the absence of effusion does not rule out the diagnosis.
4. **Therapy**
   a. **Aspirin** is used to manage post-MI pericarditis and doses as high as 650 mg every 4 to 6 hours may be needed.
   b. **Nonsteroidal antiinflammatory agents and corticosteroids should not be used to treat these patients**. These agents may interfere with myocardial healing and contribute to infarct expansion.
   c. **Colchicine** may be beneficial. Colchicine 0.6 mg every 12 hours plus conventional therapy with aspirin decreases symptom recurrence in patients with idiopathic pericarditis.

B. **Late pericarditis (i.e., Dressler's syndrome).** The incidence of Dressler's syndrome is between 1% and 3%. The syndrome occurs 1 to 8 weeks after MI. The pathogenesis is unknown, but an autoimmune mechanism has been suggested.
1. **Clinical presentation.** Patients may present with chest discomfort that suggests pericarditis, pleuritic pain, arthralgia, malaise, fever, pericardial friction rub, elevated leukocyte count, and an elevated sedimentation rate. Echocardiography may reveal a pericardial effusion.
2. **Therapy** is similar to that for early post-MI pericarditis: aspirin, colchicine, and avoidance of nonsteroidal antiinflammatory drugs and corticosteroids. However, if > 4 weeks have elapsed since the MI, nonsteroidal antiinflammatory agents and corticosteroids may be indicated for severe symptoms.

TABLE 3.4 Electrocardiographic Changes of Pericarditis

Stage I	ST elevation, upright T waves
Stage II	ST elevation resolves, upright to flat T waves
Stage III	ST isoelectric, inverted T waves
Stage IV	ST isoelectric, upright T waves

Cardiogenic Shock Complicating Acute Myocardial Infarction

I. INTRODUCTION. Left ventricular (LV) dysfunction is common after acute myocardial infarction (MI), and the severity of dysfunction correlates with the extent of myocardial injury. Cardiogenic shock is estimated to **complicate 3% to 8% of cases of acute MI** (1–3). **The mortality associated with cardiogenic shock in patients with acute MI had historically approached 80%** (1,4). Despite advancements in coronary reperfusion, **the contemporary mortality associated with MI complicated by cardiogenic shock remains at 40% to 70%** (3,5,6). **Prior MI, older age, female sex, diabetes, and anterior infarction** are risk factors for the development of cardiogenic shock after MI.

II. CLINICAL PRESENTATION. Cardiogenic shock is a clinical condition in which **inadequate tissue perfusion is the consequence of cardiac dysfunction**. It is characterized by a **reduction in cardiac output despite adequate filling pressures**. Criteria typically used to define cardiogenic shock include **systolic blood pressure < 90 mm Hg** for at least 30 minutes or need for vasopressor or intra-aortic balloon support to maintain systolic blood pressure > 90 mm Hg, **pulmonary capillary wedge pressure (PCWP) > 15 mm Hg, and cardiac index < 2.2 L/min/kg/m^2**.

- **A. Symptoms.** Patients in cardiogenic shock from LV failure typically present with **respiratory distress**. **Confusion** may occur due to inadequate tissue perfusion.
- **B. Physical findings**
  1. **Hypotension, tachycardia, confusion, diminished urine output (<30 mL/h), and cool, mottled, and cyanotic extremities** typically characterize the clinical presentation of cardiogenic shock. Peripheral pulses are often diminished in cardiogenic shock due to decreased pulse pressure **(pulsus parvus)**. In a failing left ventricle the strength of every other beat may alternate, a phenomenon known as **pulsus alternans**. A **dyskinetic segment of the ventricle** may be apparent during inspection or may be felt during palpation. An **S_3 gallop** may be heard in patients with poor LV function.
  2. Patients with acute mechanical complications of MI such as ventricular septal rupture, acute mitral regurgitation, ventricular free wall rupture, ventricular pseudoaneurysm, ventricular aneurysm, right ventricular failure, and dynamic outflow tract obstruction may present with additional physical findings as discussed in Chapter 3.
  3. Cardiogenic shock due to LV failure may cause pulmonary congestion and inspiratory rales. However, **a significant proportion of patients in the SHOCK (SHould we emergently revascularize Occluded coronaries for Cardiogenic shocK?) registry had no pulmonary congestion** (7). Neither auscultation nor chest radiograph detected pulmonary edema in 28% of the patients.
  4. A select group of patients may exhibit **preshock**. This clinical entity is characterized by signs of hypoperfusion with resting tachycardia but not frank hypotension due to a compensatory increase in systemic vascular resistance. On right heart catheterization, these patients have an ineffective cardiac index and are at high risk for in-hospital mortality.

III. RISK STRATIFICATION

- **A.** In the prereperfusion era, **Killip and Kimball** classified **four subsets of patients on the basis of clinical presentation and physical findings** at the onset of MI (4). They reported an 81% in-hospital mortality in patients with cardiogenic shock (Killip class IV). In the fibrinolytic era, the 30-day mortality rate for patients in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries 1 (GUSTO-1) trial that presented with cardiogenic shock was 58% (Table 4.1) (8). The presence of resting tachycardia and pulmonary congestion identifies patients at highest risk even in the current reperfusion era.
- **B.** In a classic study performed in the prereperfusion era, **Forrester** classified **four hemodynamic subsets of patients on the basis of PCWP and cardiac index** (Table 4.2) and determined the associated mortality in acute MI (9).
- **C.** Right heart catheterization hemodynamic parameters including stroke volume, cardiac output, and cardiac index are strong predictors of in-hospital mortality in patients presenting with MI complicated by cardiogenic shock. In the SHOCK registry, the **cardiac power index** (mean arterial pressure × cardiac index/451) in W/m^2 was the strongest independent hemodynamic correlate of in-hospital mortality (10).
- **D.** The SHOCK trial investigators have also published a **severity scoring system** to predict in-hospital mortality in patients with acute MI complicated by cardiogenic

TABLE 4.1 30-Day Mortality Based on Hemodynamic (Killip) Class in the GUSTO-1 Trial

Killip class	Characteristics	Patients (%)	Mortality rate (%)
I	No evidence of CHF	85	5
II	Rales, ↑ JVD, or S_3	13	14
III	Pulmonary edema	1	32
IV	Cardiogenic shock	1	58

CHF, congestive heart failure; ↑, increased; JVD, jugular venous distention.

Adapted from Fox AC, Glassman E, Isom OW. Surgically remediable complications of myocardial infarction. *Prog Cardiovasc Dis.* 1979;107:852-855.

shock (11). Age, shock on admission, clinical evidence of end-organ hypoperfusion, anoxic brain damage, systolic blood pressure, prior coronary artery bypass grafting, anterior MI location, and creatinine > 1.9 mg/dL are the risk factors utilized in a multivariable model. In patients with hemodynamic monitoring, age, end-organ hypoperfusion, anoxic brain damage, stroke work, and left ventricular ejection fraction < 28% are the variables considered.

IV. ETIOLOGY. Table 4.3 outlines the various etiologies of cardiogenic shock complicating acute MI. Patients with acute MI and cardiogenic shock typically have significant **left main** and **severe three-vessel coronary artery disease** and commonly have substantial involvement of the **left anterior descending artery** (12). Autopsy studies have revealed that at least 40% of the LV is affected in most patients presenting with cardiogenic shock complicating acute MI (13). Forty percent of patients have a history of prior MI. If the previous MI was large, even a small, acute MI in a nonanterior location may cause shock. **In the SHOCK registry, LV failure (79%), severe mitral regurgitation (7%), ventricular septal rupture (4%), right ventricular failure (3%), and ventricular free wall rupture (1%) were the leading causes of cardiogenic shock in acute MI** (6). **Bradyarrhythmias and tachyarrhythmias** related to acute MI can also cause cardiogenic shock. **Medications** administered for acute MI such as β-blockers, angiotensin-converting enzyme inhibitors, and morphine can cause iatrogenic shock by inducing hypotension.

TABLE 4.2 Forrester Classification

Subset	PCWP	Cardiac index	Mortality rate
I	<18	>2.2	3
II	>18	>2.2	9
III	<18	<2.2	23
IV	>18	<2.2	51

PCWP, pulmonary capillary wedge pressure.

TABLE 4.3 Causes of Cardiogenic Shock Complicating Acute Myocardial Infarction

Left ventricular failure
Right ventricular failure
Ventricular septal rupture
Acute mitral regurgitation
Ventricular aneurysm
Ventricular free wall rupture
Cardiac tamponade
Dynamic left ventricular outflow tract obstruction
Arrhythmia
Iatrogenic (e.g., β-blocker related)

In the Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT), early β-blocker use was associated with an increased risk of developing cardiogenic shock, especially when used within the first day of admission (14). **Occult bleeding** resulting from antiplatelet and anticoagulation therapies in acute MI can also result in hypotension and circulatory collapse.

V. PATHOPHYSIOLOGY. Ineffective cardiac output in the setting of cardiogenic shock results in hypotension and tachycardia. A compensatory increase in systemic vascular resistance may occur through peripheral vasoconstriction in an effort to maintain blood pressure and tissue perfusion. However, this classic paradigm has been challenged. Data from the SHOCK registry revealed that many patients with cardiogenic shock instead had low systemic resistance, similar to patients with septic shock (15). It has been postulated that a systemic inflammatory response-like syndrome with a low systemic vascular resistance may be encountered in up to one-fifth of patients with acute MI complicated by cardiogenic shock (16). Figure 4.1 provides an overview of the pathophysiology of cardiogenic shock caused by acute MI and the expansion of the paradigm to include the contribution of inflammatory mediators.

VI. LABORATORY EXAMINATION. Decreased mixed venous oxygen saturation, lactic acidosis, and elevated creatinine and liver transaminase levels are common.

VII. DIAGNOSTIC STUDIES

A. Electrocardiogram. Patients with cardiogenic shock resulting from LV failure usually have extensive electrocardiographic abnormalities consistent with massive infarction, severe diffuse ischemia, or evidence of a large, prior MI. Extensive ST-segment deviations are common. Both ST-elevation MI and non–ST-elevation MI can manifest as cardiogenic shock.

B. Chest radiography may reveal pulmonary congestion.

C. Hemodynamic monitoring with an **arterial line** and **pulmonary artery (PA) catheter** is helpful in monitoring the patient's hemodynamic status and may also identify complications of acute MI, including right ventricular infarction, acute mitral regurgitation, and ventricular septal rupture. In GUSTO-1, mortality among patients ($n = 995$) presenting with acute MI and cardiogenic shock that were managed with

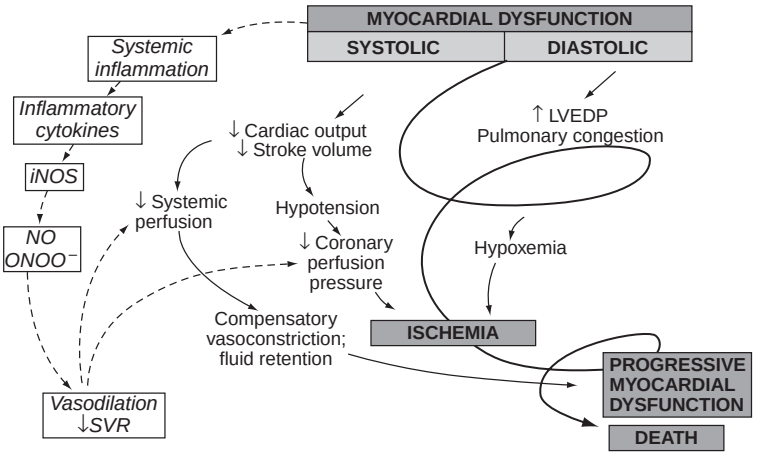

FIGURE 4.1 Expansion of the pathophysiologic paradigm of cardiogenic shock to include the potential contribution of inflammatory mediators. LVEDP, left ventricular end diastolic pressure; NO, nitric oxide; iNOS, inducible nitric oxide synthase; $ONOO^-$, peroxynitrite; SVR, systemic vascular resistance. PA catheters (45.2%) was less than among those (n = 1,406) that were not managed with PA catheters (63.4%) (17). However, the difference in part may be attributable to survivor bias as well as confounding.

D. Transthoracic echocardiography may help determine the etiology of shock as well as the extent of myocardial injury. It can identify the complications of acute MI that contribute to cardiogenic shock. It may also draw attention to additional causes of cardiogenic shock such as aortic dissection, cardiac tamponade, or pulmonary embolism.

VIII. THERAPY

A. Priority of therapy. Early revascularization is critically important in the management of patients presenting with acute MI and cardiogenic shock. The benefits of this strategy were proven in the SHOCK trial (18). Early revascularization saved 13 lives per 100 treated at 1 year compared with a strategy of medical stabilization and delayed revascularization. This strategy should be strongly considered in all patients aged < 75 years in the absence of contraindications; select older patients with good premorbid functional status also derived a similar benefit from this approach. Consequently, patients with acute MI complicated by cardiogenic shock should undergo prompt angiography for defining coronary anatomy. Subsequent revascularization should be guided by clinical presentation, extent of disease, and concomitant valvular function.

B. Percutaneous coronary intervention (PCI) of the infarct-related artery should be attempted emergently in this population. With the adoption of PCI, there has been a marked decline in the mortality of patients with acute MI complicated by cardiogenic shock. Persistence of shock following successful PCI of the infarct-related artery may be an indication to consider multivessel intervention, especially when remote ischemia in noninfarct distributions is suspected.

C. Coronary artery bypass grafting. Emergency surgical revascularization should be considered in the care of patients with severe multivessel disease or substantial left main coronary artery stenosis. It is also indicated when there is a significant concomitant valvular disease that is contributing to hemodynamic instability. Despite sicker patients with more extensive coronary artery disease being referred for coronary artery bypass grafting, mortality due to surgery in the SHOCK Trial and Registry was comparable to that of PCI. However, at many centers, there is reluctance to operate on patients in cardiogenic shock and early reperfusion is generally performed utilizing PCI.

D. Adjunctive support

1. An **intra-aortic balloon pump** (IABP) should be inserted as soon as possible in a patient with cardiogenic shock to ensure hemodynamic stability and protect end-organ perfusion. IABP support reduces afterload, improves cardiac output, and decreases the myocardial oxygen requirement by means of reduction in wall stress. An IABP is also beneficial in MI because diastolic augmentation may increase coronary perfusion in vessels that do not have a flow-limiting stenosis. Contraindications to placement include the presence of significant peripheral vascular disease, aortic dissection, and more than moderate aortic insufficiency. There are no randomized controlled trials to support the placement of an IABP in this setting. One must, however, remember that the IABP was an integral component of the early revascularization strategy observed in the SHOCK trial.
2. **Transvenous pacing.** Patients with inadequate heart rate due to bradyarrhythmia or chronotropic incompetence may require temporary pacing to increase the heart rate and augment cardiac output. **Atrial pacing** maintains atrioventricular synchrony and normal LV contraction and is preferable to ventricular pacing if atrioventricular conduction is intact.

E. Medical therapy

1. **Vasopressors.** Patients may need vasopressors to maintain an effective mean arterial pressure. **Dopamine** is started at 3 μg/kg/min and titrated to a maximal dose of 20 μg/kg/min. **Norepinephrine** is started at 2 μg/min and titrated to a maximal dose of 30 μg/min. Dopamine may be associated with higher mortality in cardiogenic shock than norepinephrine when titrated to maintain an effective mean arterial pressure (19).
2. **Inotropic agents.** Patients with severe LV failure and cardiogenic shock may require temporary support with an inotropic agent.
   a. **Dobutamine** has a positive inotropic action comparable to that of dopamine and may decrease afterload. Dobutamine is started at a dose of 2.5 μg/kg/min and increased to a maximal dose of 40 μg/kg/min.
   b. **Milrinone**, a phosphodiesterase inhibitor with inotropic and vasodilator action, may be beneficial in some patients, especially those with right ventricular dysfunction. Milrinone is given as a 50-μg/kg bolus over 10 minutes, followed by an infusion of 0.375 to 0.75 μg/kg/min. The bolus may be omitted in the care of patients with low blood pressure. Patients without adequate blood pressure may not tolerate milrinone.
   c. **Levosimendan** is an intravenous agent that increases inotropy by binding cardiac troponin C and sensitizing myofilaments to calcium. It is currently approved for use in some countries in Europe and South America but is not available for use in the United States.
3. **Vasodilators** such as **nitroglycerin** and **sodium nitroprusside** can play an important role in the management of post-MI LV failure by means of preload and afterload reduction. However, in the setting of cardiogenic shock, their use may be limited by refractory hypotension.
4. Table 4.4 summarizes the hemodynamic effects of medications used in the management of cardiogenic shock.

TABLE 4.4 Hemodynamic Effects of Medications Used to Manage Cardiogenic Shock

Medication	Preload	Afterload	Inotropy	Chronotropy
Dopamine (3–10 μg/kg/min)	0	–	++++	++
Dopamine (>10 μg/kg/min)	0	+++	+++	+++
Norepinephrine (2–300 μg/min)	0	++++	+	++
Epinephrine (0.05–1 μg/kg/min)	0	+++	+++	+++
Phenylephrine (0.5–15 μg/kg/min)	0	++++	0	–
Dobutamine (2.5–25 μg/kg/min)	–	–	++++	+++
Milrinone (0.375–0.75 μg/kg/min)	– –	– –	+++	+
Nitroglycerin (2.5–300 μg/min)	– – –	–	0	+
Nitroprusside (0.3–10 μg/kg/min)	– – –	– – –	0	+

0, no effect; –, decrease; +, increase.

IX. MANAGEMENT OF REFRACTORY SHOCK AFTER CORONARY REVASCULARIZATION

A. Triage. Patients that remain in cardiogenic shock despite coronary revascularization are best served by transfer to a facility that can provide additional adjunctive hemodynamic therapies. In addition, the facility should have an active cardiac transplant program and full-time availability of interventional cardiology, electrophysiology, cardiothoracic surgery, and neurology services.

B. Decision making. The prognosis for patients that remain in cardiogenic shock after coronary revascularization is extremely poor. However, there are patients that do ultimately recover their LV function and survive. It is often impossible to predict which patients will do well and which patients will succumb to their illness. In our institution, we often consider additional adjunctive hemodynamic therapies as a bridge to decision making.

C. Additional adjunctive hemodynamic support

1. **Percutaneous ventricular assist device (pVAD).** Traditional mechanical circulatory support from an IABP may prove insufficient in certain patients, and consideration may be given to more aggressive support with a percutaneous assist device, especially if shock persists after coronary revascularization.
   - **(a)** The **TandemHeart** (Fig. 4.2) device provides left atrial to femoral artery bypass flow at rates of up to 5.0 L/min with percutaneous access and can serve as a bridge to recovery or more definitive therapy. Limited case series from isolated centers suggest that the TandemHeart device is able to rapidly reverse the terminal hemodynamic compromise seen in patients with severe cardiogenic shock refractory to IABP and/or high-dose vasopressor support (20).
   - **(b)** The **Impella** intracardiac axial flow ventricular assist device can provide either 2.5 or 5.0 L/min support. Our experience has been that the Impella 2.5 L/min device does not provide much additional benefit beyond that of an IABP, whereas the 5.0 L/min device provides substantial adjunctive support. Currently, the Impella 5.0 L/min device requires surgical cut-down for vascular access.

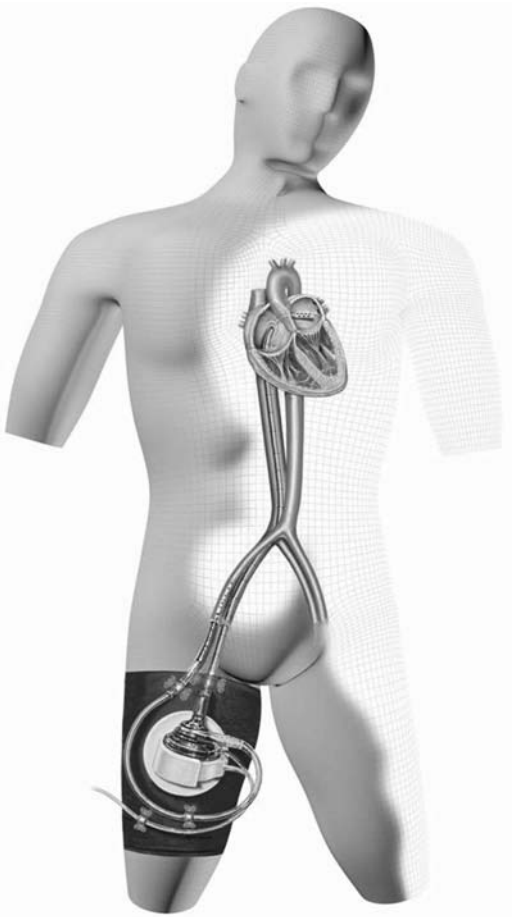

FIGURE 4.2 The TandemHeart percutaneous left ventricular assist device. (Reprinted with permission from CardiacAssist, Inc.)

2. **Extracorporeal membrane oxygenation (ECMO).** ECMO is an established therapy that can be implemented expeditiously in experienced hands. It provides hemodynamic support and as an additional advantage can support oxygenation if the lung function is compromised. We often use ECMO in our institution as a bridge in deciding whether to use more long-term therapy such as an implanted left ventricular assist device (LVAD).
3. **Left ventricular assist device.** Surgical LVAD therapy is often utilized in advanced LV failure as a destination therapy or as a bridge to transplant. In patients presenting with acute MI complicated by cardiogenic shock, LVAD therapy is a consideration. However, other temporizing measures such as pVAD or ECMO are often considered first.

Venu Menon

Post–Myocardial Infarction Risk Stratification and Management

I. INTRODUCTION. More than 1.5 million patients will have an acute coronary syndrome (ACS) in the United States each year. At least 1 million will have evidence of myocardial infarction (MI), for which mortality and morbidity remain considerable. Although patient outcomes have improved, well-documented therapies are still often underprescribed. Besides identifying patients with MI, the goals of the physician must be to successfully stratify patients according to risk, implement medical interventions, and initiate risk factor modification during the initial hospitalization.

II. RISK STRATIFICATION. Post-MI risk stratification identifies patients at high risk for subsequent cardiovascular events who will benefit from revascularization.

A. Age is the most important predictor of mortality after MI. The average age of patients with first MI is approximately 65 years. Although older patients are at greatest risk and may benefit most, they receive less aggressive treatment compared with younger patients, who have the lowest overall mortality.

B. Assessment of left ventricular (LV) function

1. **LV function** is the second most important predictor of mortality after MI. An inverse relation exists between left ventricular ejection fraction (LVEF) and mortality. Mortality is greatest for patients with an LVEF < 40%.
2. Assessment of LV function is indicated for all patients diagnosed with MI. Echocardiography is often utilized to assess LV function because it is readily available, is relatively inexpensive, and can assess concomitant valvular function as well as mechanical complications of MI. Left ventriculography performed during diagnostic catheterization, or ascertained by radionuclide ventriculography, and cardiac magnetic resonance may also be utilized to evaluate LV function. Availability, local expertise, and cost are important considerations when deciding which procedure to use.

C. Other indicators. Biomarkers are useful in further risk-stratifying patients after MI. **Cardiac troponin** elevation identifies high-risk patients and incremental increases in troponin levels predict higher mortality in patients with ACS. Elevated serum levels of high-sensitivity **C-reactive protein** and **B-type natriuretic peptide may also provide prognostic information**. New **ST-segment changes**, both elevation and depression, portend higher risk of death, heart failure, recurrent ischemia, and severe coronary artery disease (CAD). **Electrical instability**, such as ventricular arrhythmias and atrial fibrillation, are associated with increased risk. Anterior MI, renal insufficiency, poor glycemic control, and anemia are also associated with worse outcomes.

D. Risk models. Various models utilize a combination of the aforementioned risk factors to quantitate a predictive score of patient risk for subsequent cardiac events

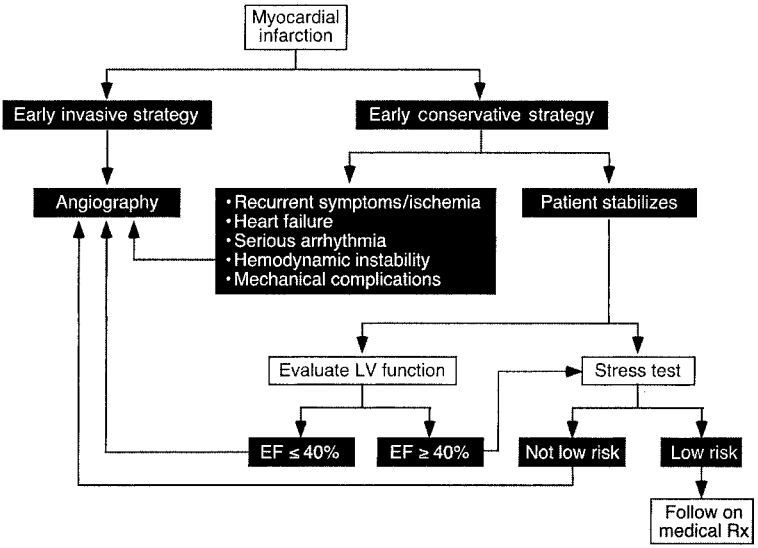

FIGURE 5.1 Post–myocardial infarction risk stratification. LV, left ventricular; EF, ejection fraction.

and mortality. Examples include Thrombolysis in Myocardial Infarction (TIMI), Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio (GISSI), and the Global Registry of Acute Coronary Events (GRACE).

E. Assessment of residual ischemia (Fig. 5.1). The extent of CAD and the presence of residual ischemia are two strong predictors of mortality among patients who have had an MI. For this reason, post-MI patients who have not undergone angiography should undergo stress testing before discharge or shortly thereafter (preferably within 3 to 7 days post-MI). Non–ST-elevation ACS patients at low or intermediate risk who do not have ongoing ischemia or heart failure for at least 12 to 24 hours are also candidates for submaximal stress testing. Because of increasing availability of percutaneous revascularization and growing implementation of a pharmaco-invasive strategy for ST-elevation MI (STEMI) patients who receive thrombolytics, most patients with STEMI undergo angiographic definition. Stable STEMI patients who have not undergone catheterization should undergo stress testing to assess for ischemia 2 to 3 days after the index event.

1. **Submaximal exercise stress testing is optimal for noninvasive risk stratification.** This test provides considerable prognostic information, assesses functional capacity and efficacy of medical therapy, and can guide cardiac rehabilitation after discharge. Patients who achieve at least 3 metabolic equivalents (METs) of the task have a good prognosis. Inability to achieve 3 METs, hypotension during exercise, or marked ST-segment depression or elevation is an indication for coronary angiography.
2. **Stress imaging with echocardiography** or **radionuclide imaging is** recommended in patients who have uninterpretable electrocardiograms (e.g., baseline ST-T changes, LV hypertrophy, intraventricular conduction delays, paced rhythm, or digoxin-related effects). Addition of either imaging modality increases both the sensitivity and specificity of detecting CAD. Patients with

severe resting or exercise-induced LV dysfunction or evidence of extensive ischemia (large perfusion defect, multiple moderate perfusion defects, wall motion abnormalities at low-dose dobutamine or low heart rate, and stress-induced LV dilation) are considered high risk and should undergo coronary angiography.

3. **Dobutamine, adenosine, and dipyridamole** are pharmacologic agents used safely in conjunction with imaging for post-MI stress testing if a patient cannot exercise (see Chapter 6).

III. THERAPY AFTER MI

A. Coronary angiography

1. **Indications**
   - **a.** Coronary angiography is indicated in patients with STEMI as well as in those with non-STEMI who are at high risk for clinical events, recurrent angina or ischemia on medical therapy, or high-risk findings on noninvasive stress testing.
   - **b.** An **"early invasive strategy" utilizing coronary angiography** is the preferred approach for patients at high risk for clinical events, including a high-risk score, elevated troponin, congestive heart failure, mechanical complications, and electrical or hemodynamic instability.
   - **c. Patients with a history of prior revascularization,** either percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG), should generally be referred for angiography.
   - **d.** Coronary angiography to identify potential bypass targets is generally preferred prior to open heart surgery if a patient has surgical anatomy or has a mechanical complication post-MI requiring surgical intervention. Such complications of MI include ventricular septal rupture, LV aneurysm, and acute mitral regurgitation due to papillary muscle rupture. In rare instances when hemodynamic instability precludes angiography, the surgeon may bypass all or selected coronary arteries.
2. **Contraindications.** Catheterization should not be performed on patients who are ineligible for surgical or percutaneous revascularization because of severe comorbid conditions or who do not consent to angiography because of personal preference.
3. **Controversy.** Low-risk, asymptomatic patients who have sustained an uncomplicated MI generally have a good long-term prognosis and may not need to undergo angiography. These patients presumably are those without high-risk features on noninvasive stress testing who will receive aggressive medical therapy and risk factor modification.
4. **PCI.** A new era of PCI therapy that includes novel anticoagulants, antiplatelet agents, and newer generation drug-eluting stents continues to significantly enhance the options and outcomes for post-MI patients undergoing revascularization.

B. CABG after MI can be divided into two categories: emergent and elective.

1. **Emergent CABG.** The indications and management considerations for emergent CABG are discussed in Chapter 1.
2. **Elective CABG.** CABG has been shown to provide a survival benefit for patients with left main (> 50% stenosis) or extensive three-vessel CAD. Surgical revascularization remains preferable for patients with severe LV dysfunction, diabetes, or two-vessel disease with proximal left anterior descending involvement and either high-risk noninvasive stress test results or LV dysfunction. However, the Arterial Revascularization Therapies Study (ARTS) demonstrated no significant difference in mortality, MI, or stroke among patients with multivessel disease and normal to moderately decreased LV function randomized to CABG versus PCI. The Synergy between Percutaneous Coronary Intervention with Taxus and

Cardiac Surgery (SYNTAX) trial evaluated PCI versus CABG for three-vessel or left main disease and nearly 30% of the patients had ACS. This trial demonstrated equivalent cumulative rates of major adverse cardiac or cerebrovascular events in the low (0 to 22) and intermediate (22–32) SYNTAX score patients, though there was a higher rate of adverse events in the high (≥33) SYNTAX score patients who underwent PCI. Target vessel revascularization was higher in the PCI group but stroke rate was higher in the CABG group.

3. **Operative risk.** No prospective, randomized trials have been performed to determine the optimal timing of elective CABG after MI. Most data suggest that CABG 3 to 7 days after MI is associated with a low operative mortality similar to that of elective bypass in patients without recent infarction. **Operative risk increases** among patients with LV dysfunction, advanced age, and multiple comorbid conditions (e.g., diabetes mellitus, chronic obstructive pulmonary disease, and chronic renal insufficiency). Emergent CABG and reoperations on patients with prior open heart surgery are associated with a higher operative mortality. If initiated previously, **clopidogrel** should be held for at least **5 days** prior to surgery and **prasugrel** for at least **7 days** prior to decrease perioperative bleeding risk. Ticagrelor is a reversible inhibitor of the adenosine diphosphate (ADP) receptor $P2Y_{12}$ that is more rapid acting and potent than clopidogrel. There was initial hope that the use of ticagrelor in patients with ACS undergoing urgent bypass surgery could reduce the time from cessation of antiplatelet agents to the time of surgery to just 2 or 3 days, given the more rapid reversal of platelet inhibition. However, results from the Study of Platelet Inhibition and Patient Outcomes (PLATO) demonstrated no difference in TIMI major bleeding or transfusion rates in patients with ACS who stopped clopidogrel 5 days prior to CABG compared with those who stopped ticagrelor 24 to 72 hours before surgery. Bleeding rates were equivalent even when surgery occurred 1 to 3 days after discontinuation of antiplatelets. Therefore, current ACC/AHA guidelines recommend **withholding ticagrelor for at least 5 days** prior to elective open heart surgery.

IV. SECONDARY PREVENTION

A. Smoking cessation is mandatory. Smoking doubles the rate of reinfarction and death after MI, causes coronary artery spasm, and reduces the effectiveness of β-blocker therapy. The risk reduction attributed to smoking cessation is rapid and nearly equals that of post-MI patients who never smoked in only 3 years. Half of all patients who stop smoking after MI will begin smoking again within 6 to 12 months. Many approaches to smoking cessation have been attempted, including pharmacologic therapy, formal smoking cessation programs, hypnosis, and abstinence.

1. **Nicotine substitutes** can be delivered by a variety of vehicles, including transdermal patches, chewing gum, nasal spray, and inhalers. These systems can deliver 30% to 60% of the nicotine of cigarettes. Although nicotine substitutes are not recommended for the acute phase of MI, use of these agents is safe in later phases. Patients who start smoking again should discontinue the use of nicotine substitutes.
2. **Pharmacotherapy. Bupropion** appears to be an effective aid in smoking cessation. The dose is doubled after 3 days and it is then taken twice daily for 7 to 12 weeks. Patients set a goal to stop smoking 1 to 2 weeks into therapy. **Varenicline**, a partial agonist of nicotine receptors, provides nicotine stimulation while blocking cigarette nicotine effects. In a head-to-head trial, varenicline was more effective than bupropion at the 12-week time period, but data suggest no significant difference in rates of abstinence at 1 year. In addition, the FDA issued a communication in 2011 warning that varenicline may increase the risk of cardiovascular events.

3. **Recommendations.** Physicians can aid patients in their effort to stop smoking by using a stepped approach with education and a firm recommendation to quit smoking, devising a plan, and reinforcing the need to quit. Patients who are likely to relapse are older, less educated, or heavy smokers. Formal smoking cessation programs have been shown to have high rates of patient abstinence. Coinhabitants should also stop smoking to increase the likelihood of success.

B. Lipid management

1. **Low-density lipoprotein (LDL).** Most patients with acute MI have abnormal lipid profiles. Several large, secondary prevention trials have demonstrated that lowering of lipids can reduce the incidence of future mortality, reinfarction, and stroke.
   a. **Diagnostic testing.** All patients who have had an MI should have a complete lipid panel (e.g., total cholesterol, LDL cholesterol, high-density lipoprotein (HDL) cholesterol and triglycerides (TG) determined during hospitalization.
   b. **Diet.** Current ACC/AHA guidelines recommend that all patients should start the AHA step II diet (< 7% of total calories as saturated fat and < 200 mg/d cholesterol). However, adherence to step II diet is low.
   c. **Therapy.** The National Cholesterol Education Program III **(NCEP III)** recommends a target LDL cholesterol level < 100 mg/dL, with a goal of < 70 mg/dL in very high risk patients (e.g., post-MI). Given the results of the Heart Protection Study (HPS), a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor, or **statin, should be initiated in all patients irrespective of LDL levels,** owing to potential benefits in addition to lipid lowering, including anti-inflammatory and antithrombotic effects. The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) and Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) trials demonstrate that **early initiation of aggressive lipid-lowering statin therapy** during an ACS is associated with a **reduction in major cardiovascular events, including death**. Long-term compliance with statins is improved by in-hospital initiation of therapy (77% vs. 40%). Other therapies include bile acid sequestrants, niacin, gemfibrozil, moderate alcohol consumption (particularly red wine), and exercise. These may be used in conjunction with statin therapy.
2. **HDL.** Low HDL cholesterol level is an independent risk factor for MI. The NCEP III recommends an HDL level of at least 40 mg/dL. Consideration can be given to therapy with exercise, niacin, or gemfibrozil. An earlier trial, the Investigation of Lipid Level Management to Understand Its Impact in Atherosclerotic Events (ILLUMINATE), compared the use of a cholesteryl ester transfer protein (CETP) inhibitor torcetrapib plus statin versus statin alone and demonstrated increased HDL levels but significantly more adverse cardiovascular events and death from all causes in the torcetrapib group. A more recent trial with a newer drug anacetrapib, the Determining the Efficacy and Tolerability of CETP Inhibition with Anacetrapib (DEFINE) study, has corroborated the beneficial effect on HDL and LDL but without an increase in cardiovascular side effects. Randomized clinical trials are currently evaluating the role of CETP inhibitors in event reduction.
3. **Triglycerides.** Hypertriglyceridemia may be an independent risk factor for CAD, commonly accompanied by low HDL levels or diabetes. Patients with TG levels above 200 mg/dL should be counseled to achieve non-HDL levels below 130 mg/dL. Fenofibrate or gemfibrozil can be added when TG levels exceed 200 mg/dL, particularly if a low HDL level is concurrent. Fibrates and high doses of statins can increase the risk of myopathy and should be avoided if possible. Omega-3 fatty acids may also be beneficial. Niacin can also be

considered for treatment of hypertriglyceridemia, but results from the recent Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) trial challenge the efficacy of extended-release niacin in preventing cardiovascular events. In this trial, even though extended-release niacin, when added to statin therapy, was able to decrease TG levels from 164 to 122 mg/dL, decrease LDL from 74 to 62 mg/dL, and raise HDL from 35 to 42 mg/dL, there was no difference in the primary end point (mean follow-up period of 3 years) consisting of a composite of cardiovascular outcomes.

C. Diabetes management. The American Diabetes Association recommends treating glucose levels with the goal of lowering the hemoglobin A1c to below or around 7% with the intent of decreasing micro- and macrovascular events. However, the concept of "intensive" glucose control has been challenged recently by trials demonstrating adverse events associated with this strategy in both the inpatient and outpatient settings. The Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial enrolled critically ill patients in an ICU setting and demonstrated increased mortality in the group randomly assigned to maintaining target glucose levels between 81 and 108 mg/dL versus a target glucose level of 180 mg/dL or less in the comparison group. Likewise, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, a large randomized study of over 10,000 outpatients, was discontinued due to excess mortality in the intensive therapy group assigned to achieve a hemoglobin A1c < 6% compared with the standard therapy group whose target A1c was between 7% and 7.9%.

D. Antiplatelet therapy

1. All patients who have had an MI should take **aspirin** upon presentation and continue indefinitely unless there are absolute contraindications. Aspirin therapy after MI results in a mortality reduction of 25 lives per 1,000 patients treated. Aspirin reduces the rates of vascular mortality, nonfatal stroke, and nonfatal MI. Doses of at least 75 to 162 mg daily are recommended for all patients presenting with ACS. Patients receiving dual antiplatelet therapy (e.g., aspirin plus thienopyridines) have fewer side effects, such as bleeding, at lower aspirin doses.
2. **Thienopyridines** (i.e., ticlopidine, clopidogrel, prasugrel, and ticagrelor) inhibit platelets via adenosine diphosphate antagonism. Clopidogrel is favored over ticlopidine because of a greater incidence of hematologic dyscrasia associated with ticlopidine. In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, the combination of clopidogrel and aspirin was given early for ACS without ST-segment elevation, thereby reducing cardiovascular death, MI, stroke, in-hospital ischemia, and revascularization, with benefit seen at 1 year of therapy. The Clopidogrel as Adjunctive Reperfusion Therapy (CLARITY) trial and Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) demonstrated the benefit of clopidogrel in patients with ST-elevation MI with reperfusion via lytics or PCI. Prasugrel is a more potent and more rapid inhibitor of ADP than clopidogrel, and the Trial to Assess Improvements in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-TIMI (TRITON-TIMI) 38 trial demonstrated a reduction in the composite end point of death from all causes, nonfatal MI, or urgent target vessel revascularization with use of prasugrel compared with clopidogrel. Absolute contraindications to prasugrel use include prior stroke or transient ischemic attack. Patients with elevated risk of bleeding with prasugrel include those above age 75 years and those who weigh < 60 kg, and caution should be taken before prescribing this drug to these patients. Ticagrelor is the first reversible inhibitor of the $P2Y_{12}$ receptor and its action is more rapid and potent than that of clopidogrel. The PLATO trial demonstrated the superiority of ticagrelor over clopidogrel in reducing a composite of death from vascular causes, MI, or stroke in patients with ACS. It was also able

to demonstrate a greater reduction in the secondary end point of death from any cause using ticagrelor versus clopidogrel. Opinions vary as to whether to withhold thienopyridine loading prior to arrival in the catheterization lab in patients who are likely to require CABG because of an increased risk of bleeding and possible delay in surgery. If a patient requires urgent surgery, then clopidogrel and ticagrelor should be held for at least 24 hours to reduce the risk of major bleeding.

3. **Adding other medications,** such as sulfinpyrazone and dipyridamole, has not been shown to be more efficacious than aspirin alone and is not recommended for patients who have had an MI.

E. Warfarin sodium

1. **Patients** with a large anterior MI and LV thrombus treated with warfarin are at decreased risk for embolic stroke. Randomized trials do not exist, but many physicians recommend 6 weeks of warfarin therapy for this group of patients. This may assist in stabilization and endothelialization of the thrombus.
2. Data for the routine use of warfarin in conjunction with aspirin for secondary prevention of reinfarction are conflicting. The Combination Hemotherapy and Mortality Prevention (CHAMP) study and the Coumadin Aspirin Reinfarction Study (CARS) trial found no benefit from the addition of warfarin to standard aspirin therapy. However, combination therapy with aspirin and warfarin decreased infarct-related artery reocclusion and recurrent events in the Antithrombotics in the Prevention of Reocclusion in Coronary Thrombolysis (APRICOT 2) trial. The routine use of warfarin after MI is currently not recommended except for other established indications for anticoagulation, such as atrial fibrillation or prosthetic heart valves. Patients with concomitant use of dual antiplatelet agents for coronary disease are at significant risk for bleeding and hence this therapy should be used judiciously in these patients.

F. β-Blockers

1. **Indications.** β-Blockers are anti-ischemic, antihypertensive, and antiarrhythmic and they reduce LV wall stress. Mortality reduction results from decreased risk of sudden death, non–sudden cardiac death (SCD), and nonfatal infarction. Overall, the use of β-blockers reduces post-MI events by approximately 20%.
   a. **The beneficial effects of β-blockers are greatest among patients who are at high risk,** such as patients with anterior infarction, complex ventricular ectopy, advanced age, and LV dysfunction. In the COMMIT trial, metoprolol given at presentation significantly reduced reinfarction and ventricular fibrillation in patients with acute MI who were hemodynamically stable; mortality benefit was not significant and this was probably the result of a net hazard during days 0 to 1 for patients presenting with New York Heart Association (NYHA) class III or IV heart failure. Several studies have found that only 50% of patients who sustain an MI actually receive β-blockers. **β-Blockers should be started as soon as possible in hemodynamically stable patients with MI** and should be continued indefinitely. Moderate LV dysfunction and compensated congested heart failure are not contraindications to β-blocker treatment.
   b. **β-Blockers** without intrinsic sympathomimetic activity, such as carvedilol, metoprolol, propranolol, timolol, and atenolol, appear to have the greatest benefit. Reduction in heart rate seems to be important in achieving a mortality benefit.
2. **Contraindications.** Relative contraindications include second- or third-degree heart block, severe asthma, severe chronic obstructive pulmonary disease, severe or decompensated congestive heart failure, heart rate < 60 beats/min, hypotension with systolic blood pressure < 120 mm Hg, or other signs of a low-output state. In patients with heart rate > 100 beats/min, cardiogenic shock should be

ruled out by history and examination before administering β-blockers. Diabetes is not an absolute contraindication; however, the dose of the β-blocker may have to be reduced or discontinued if hypoglycemic episodes are frequent or severe.

G. Angiotensin-converting enzyme (ACE) inhibitors

1. **Indications.** Ventricular remodeling can be attenuated by ACE inhibitors, reducing ventricular dilation and development of congestive heart failure. During infarction, the expression of ACE increases within the myocardium. Several large randomized clinical trials have demonstrated that ACE inhibitors reduce mortality. These trials include Survival and Ventricular Enlargement (SAVE), Acute Infarction Ramipril Efficacy (AIRE), and Trandolapril Cardiac Evaluation (TRACE). The greatest benefit was found among patients with large areas of infarction, anterior infarction, and infarction that impaired LV function. **ACE inhibitor therapy should be considered in all patients after an acute MI** in the absence of contraindications. Therapy should be continued indefinitely in the setting of LV dysfunction (ejection fraction [EF] < 40%), heart failure, hypertension, or diabetes, although the ACC/AHA guidelines give class IIa recommendation for indefinite therapy in all patients after MI regardless of LV function or comorbidities. Angiotensin receptor blockers (ARBs) may be substituted if ACE inhibitors are not tolerated. The Valsartan in Acute Myocardial Infarction (VALIANT) trial evaluated post-MI patients with clinical signs of heart failure and low EF (< 35% by echo or angiography or < 40% by radionuclide ventriculography). Even though this study did not support superiority of valsartan therapy, it demonstrated noninferior mortality outcomes between groups treated with valsartan, captopril, or the two combined. However, adverse events including hypotension and medication dose reductions due to renal causes were more frequent in the valsartan and valsartan plus captopril groups. Cough, rash, and taste disturbances were more commonly reported in the captopril group.
2. **Side effects** include cough, worsening renal function, hypotension, and angioedema. Adverse events, especially renal impairment and hypotension, may be worse when ACE inhibitors and ARBs are used concomitantly, as was shown in the Ongoing Telmisartan Alone and in Combination with Rampril Global End Point Trial (ON TARGET) and VALIANT trials.

H. Aldosterone antagonists

1. **Indications.** The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) trial demonstrated that eplerenone, when added to optimal medical therapy in post-MI patients with an EF of 40% or less, reduced the risk of death from any cause as well as the risk for a combination of death from cardiovascular causes and hospitalization for cardiovascular events. Optimal medical therapy included ACE inhibitors, ARBs, β-blockers, and coronary reperfusion.
2. **Contraindications.** Because of its diuretic property and effect on the renin–angiotensin–aldosterone neurohormonal system, eplerenone should not be used in patients with renal dysfunction (creatinine > 2.5 mg/dL) or hyperkalemia (serum potassium > 5.0 mmol/L).

I. Calcium channel blockers. The preferred agent after ACS is a β-blocker unless truly contraindicated. Calcium channel blockers are reserved for patients with **refractory angina** and not recommended for routine use after MI by the ACC/AHA guidelines. Longer acting preparations should be used if necessary, whereas short-acting dihydropyridine antagonists should be avoided.

1. **Indications.** The use of calcium channel blockers should be limited to patients with refractory angina or rapid atrial arrhythmias or to patients with clear contraindications to the use of β-blockers.
2. **Contraindications.** Calcium channel blockers should be avoided in patients with congestive heart failure or high-degree atrioventricular block after an MI.

Short-acting dihydropyridine antagonists, such as nifedipine, may increase the risk of death or infarction after MI. Short-acting nifedipine may be especially harmful to patients with hypotension or tachycardia and can induce coronary steal or reflex sympathetic activation, which increases myocardial oxygen demand. Verapamil and diltiazem are contraindicated in the care of patients with LV dysfunction or congestive heart failure after MI. These agents may be useful in patients with contraindications to β-blockers who do not have LV dysfunction or congestive heart failure. Few data are available for the effect of the second-generation agents, amlodipine and felodipine, on survival after MI.

J. Estrogen replacement therapy. The Heart and Estrogen/Progestin Replacement Study (HERS) found no benefit from hormone replacement therapy as secondary prevention for coronary disease, as the therapy was associated with an early increase in death and MI. The Women's Health Initiative (WHI) also observed an increased risk of cardiovascular events and breast cancer with hormone replacement therapy. Initiation of estrogen for primary and secondary prevention of cardiovascular disease is not recommended and should be discontinued at the time of MI.

K. Antioxidants. Previous epidemiologic studies suggested that vitamin E, vitamin C, and β-carotene were associated with a lower incidence of CAD, but more recent studies failed to corroborate these findings. The HPS did not demonstrate a mortality or cardiovascular benefit from antioxidant therapy. Several other large randomized trials have failed to show either primary or secondary benefit for other similar vitamin supplementation strategies. The ACC/AHA guidelines, therefore, do not support the use of vitamin C or vitamin E, β-carotene, or folate with or without B_6 and B_{12}, for primary or secondary prevention.

V. PREVENTION OF SCD AFTER MI

A. Risk stratification for SCD

1. **All patients are at risk** for SCD after MI, with the greatest risk encountered during the first year (3% to 5%), most commonly due to ventricular arrhythmias.
2. **Reduced LV function (< 40%)** remains the best predictor of mortality. Measurement of LV function soon after MI may reflect myocardial stunning, so echocardiography should be re-measured again at the time of possible implantable cardioverter defibrillator (ICD) implantation, usually 40 days after MI for primary prevention or 3 months if reperfused after MI, via either PCI or CABG.
3. Many studies have found that patients who have more than six premature ventricular contractions per hour have a 60% relative increased risk for SCD. Patients with ventricular fibrillation or sustained ventricular tachycardia more than 48 hours after MI also are at increased risk. Monomorphic ventricular tachycardia is a manifestation of scar-related reentrant ventricular tachycardia.
4. Various techniques have been tested to identify patients at increased risk for SCD, but none is sensitive enough to be recommended for routine use. Signal-averaged ECG, heart rate variability, QT-interval dispersion, and baroreflex sensitivity are noninvasive tests, with each test having a low (< 30%) positive predictive value. Repolarization alternans (T-wave alternans) appears to have a higher sensitivity and specificity for inducible ventricular arrhythmia during electrophysiologic testing. Still invasive electrophysiologic testing has a low predictive value for future cardiac events. Consequently, **these modalities are not recommended for routine post-MI risk stratification**.

B. Therapy

1. The only medications proven to reduce risk for SCD are **β-blockers**. All patients should receive β-blockers after an MI unless absolutely contraindicated.
2. **Other medications. Amiodarone** has multiple antiarrhythmic effects, but is primarily classified as a class III agent. Trials of amiodarone in the care of

patients who have had an MI with LVEF < 40% have shown conflicting results, although a significant reduction in mortality has not been demonstrated. Amiodarone is still the preferred antiarrhythmic therapy for symptomatic or sustained ventricular arrhythmias in post-MI patients. Lidocaine is sometimes used as an alternative to amiodarone, but it should not be administered without documented ventricular tachycardia. Likewise, the prophylactic use of sotalol after MI has been associated with increased mortality. The use of type IC antiarrhythmic agents (i.e., encainide, flecainide, and propafenone) after MI is contraindicated.

3. **Implantable cardioverter-defibrillator. Early implantation of an ICD after MI has not been shown to be beneficial.** The Defibrillator IN Acute Myocardial Infarction Trial (DINAMIT) found no mortality benefit despite a reduction in arrhythmogenic death when ICDs were implanted within 40 days after MI despite LVEF < 35%. The Immediate Risk-Stratification Improves Survival (IRIS) trial enrolled patients at increased risk for sudden death within 31 days of an MI. Such patients were those with an EF = 40% and a heart rate > 90 beats/min or those with evidence of nonsustained ventricular tachycardia on ECG or holter monitor, or both. Overall mortality was not reduced in those in whom an ICD was implanted compared with the group treated with medical therapy. On the contrary, the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II) investigators and others demonstrated a survival benefit in patients with LV dysfunction and previous MI receiving a prophylactic ICD (see Chapter 23). The Multicenter Unsustained Tachycardia (MUST) trial noted improved survival with ICD implantation in patients who had inducible ventricular arrhythmias with electrophysiologic (EP) study. Therefore, class I indications for ICD therapy post-MI include patients with ischemic cardiomyopathy EF < 35% with NYHA class II or III symptoms at least 40 days post-MI, ischemic cardiomyopathy EF < 30% with NYHA class I symptoms at least 40 days post-MI, and ischemic cardiomyopathy EF < 40% with inducible ventricular fibrillation or sustained ventricular tachycardia on EP study. Patients who undergo either percutaneous or surgical revascularization after MI should have an assessment of LV function after 3 months to help determine the appropriateness of ICD implantation.

VI. THERAPY AND PREVENTION AFTER HOSPITAL TREATMENT

A. Cardiac rehabilitation programs seek to improve the biopsychosocial aspects of patients after MI by addressing the benefits of exercise, weight loss, proper diet, smoking cessation, and good mental health. Both randomized data and meta-analyses have demonstrated a mortality benefit associated with cardiac rehab in patients after MI.

1. Formal rehabilitation programs use **exercise and patient education** to help patients modify their lifestyles. The benefits of cardiac rehabilitation include improvement in a patient's commitment to treatment, increased functional capacity, and reduced likelihood of readmission for recurrent ischemia. The **social support** offered is associated with a 25% reduction in both cardiac and all-cause mortality. Depression after MI is common, and patients must be screened during follow-up. Depression is also an independent risk factor for mortality, possibly by decreasing commitment to therapy and exercise. There are limited data regarding the safety and efficacy of antidepressant medications in the post-MI setting. In a small study, sertraline was found to be safe and efficacious for the treatment of major depressive disorder after ACS.
2. **Home programs and family care.** Although cardiac rehabilitation has been shown to have many benefits, less than one-half of patients who have had an MI participate in formal programs. Home programs may be helpful, but they do not provide the social network found in group rehabilitation programs. Because most cardiac arrests after MI occur within 18 months after discharge, family members should be encouraged to learn basic cardiopulmonary resuscitation.

B. Soon after receiving the diagnosis of MI, patients should be counseled regarding **lifestyle modification** to improve weight control, diet, exercise, lipid control, blood pressure, and smoking cessation.

1. Optimal control of hypertension and diabetes should be achieved. The Diabetes Control and Complication Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) determined the need for strict glucose control of insulin and non–insulin-dependent diabetes. Improvement in serum glucose levels decreases the progression of microvascular complications. In both trials, a trend toward decreased microvascular events among the groups that received aggressive treatment was observed.
2. **Weight reduction.** Among adults in the United States, approximately two-thirds of the population, or nearly 130 million persons, are overweight (i.e., body mass index > 25 kg/m^2). Patients should be encouraged to achieve (or maintain) an ideal body weight. All patients should begin an AHA step II diet to achieve lipid goals. Fewer than 50% of patients comply with step II diet, and many patients will need additional pharmacologic therapy to manage hyperlipidemia.
3. **Resumption of daily activities**
   a. At discharge, all patients who have had an MI should receive information regarding resumption of sexual activity, driving, work, and exercise.
   b. **Sexual activity** can be resumed within a week for most patients. Oral phosphodiesterase inhibitors **are absolutely contraindicated in patients on concomitant nitrate therapy. Nitrates should not be used** within 24 hours of sildenafil and 48 hours of tadalafil. Vardenafil has a similar half-life as sildenafil and thus similar precautions should be taken. **Driving** can also be resumed within a week. Most patients who have had an MI who do not have symptoms can **return to work** within 2 weeks.
   c. A patient's performance on an **exercise test** can be used to generate an activity prescription. Patients who can perform at least 5 METs on a submaximal exercise test without marked ST-segment depression or development of angina have a good long-term prognosis.
   d. Because of the lowered oxygen tension in most commercial aircraft (pressurized to 7,500 to 8,000 feet), only patients in stable condition should **travel by plane** within the first 2 weeks after MI. They should carry sublingual nitroglycerin and request a wheelchair for transportation.

CHAPTER 6

Amar Krishnaswamy
Samir R. Kapadia

Stable Angina

I. INTRODUCTION. Angina pectoris, derived from the Greek "ankhon" (strangling) and the Latin "pectus" (chest), is the term used to describe the syndrome of chest discomfort resulting from myocardial ischemia. Angina is characterized as stable or unstable on the basis of symptom pattern.

A. Anginal symptoms are defined as stable if there is no substantial change in symptoms over several weeks. Symptoms of stable angina can fluctuate from time to time, depending on myocardial oxygen consumption, emotional stress, or change in ambient temperature. In general, the clinical definition of stable angina pectoris closely correlates with the stability or quiescence of an atherosclerotic plaque and decreased clinical risk.

B. Angina is said to be unstable when the symptom pattern worsens abruptly (increase in frequency and duration) without an obvious cause of increased myocardial oxygen consumption. Similarly, the onset of rest angina in a patient for whom angina was previously provoked by some degree of exertion may signal an unstable syndrome.

C. For some patients with new-onset angina that has been stable over a few weeks, clear distinction between stable and unstable angina is not possible. These patients can be considered to be in an intermediate stage between unstable and stable angina.

II. CLINICAL PRESENTATION. For most patients with chest pain, the diagnosis of angina pectoris can be made with careful history taking. The presence of risk factors for coronary artery disease (CAD), such as hypertension, diabetes mellitus, smoking, family history, hyperlipidemia, claudication, and advanced age, increases the likelihood that the chest pain is being caused by myocardial ischemia.

A. Signs and symptoms. The constellation of symptoms characteristic of angina pectoris includes the following four cardinal features.

1. **Location.** Discomfort is commonly located in the retrosternal area with radiation to the neck, shoulders, arms, jaws, epigastrium, or back. In some instances, it involves these areas without affecting the retrosternal area.
2. **Relation to a trigger.** Symptoms are typically triggered by physical activity, emotional stress, exposure to cold, consumption of a heavy meal, or smoking.
   a. Some patients will experience the resolution of angina despite continued exertion, which is known as the walk-through phenomenon. Others may experience the warm-up phenomenon, in which an initial exertion produces angina but a similar second exertion does not reproduce anginal symptoms. These circumstances probably result from the recruitment of collateral coronary flow during the initial episode of ischemia.
   b. Decubitus angina, which is a less common manifestation, occurs with a change in posture and is believed to be caused by a shift in blood volume. Nocturnal angina, which occurs at night, is frequently associated with nightmares and tachyarrhythmias.
3. **Character.** Most patients describe angina as a vague chest discomfort. They describe it as a squeezing, burning, tight, choking, heavy, and occasionally hot or cold sensation. Many patients do not perceive angina as pain per se. Some patients may experience dyspnea, profound fatigue, weakness, lightheadedness, nausea, diaphoresis, altered mental status, or syncope in the absence of any chest discomfort. These symptoms are often referred to as anginal equivalents. Noncardiac causes of chest pain (gastrointestinal, respiratory, musculoskeletal, etc.) may be indicated by fleeting chest pain, unrelenting chest pain not affected by activity, antecedent chest trauma, association with food intake, location inferior to the umbilicus, pleurisy, etc.
4. **Duration.** The chest pain associated with ischemia typically lasts 3 to 5 minutes. Ischemic pain usually does not last more than 30 minutes without causing myocardial infarction (MI). Chest pain triggered by emotional distress tends to last longer than that triggered by exercise. Chest pain that lasts < 1 minute is unlikely to be of cardiac origin, especially when it is not associated with other typical symptoms or findings.
5. It should be stressed that women may present with symptom constellations that may be atypical in location or quality in comparison to the symptoms described by men or manifest as anginal equivalents such as nausea or dyspnea.
6. Chest pain is defined as "typical angina" if it consists of characteristic substernal discomfort, is provoked by stress, and is relieved by rest or nitroglycerin. It is considered "atypical" if it involves two or less of the previously mentioned criteria.
7. **Classification.** Various classifications are available to assess the severity and to predict the outcome among patients with angina. The Canadian Cardiovascular Society classification is the most popular one (Table 6.1). Other classification systems include the Specific Activity Scale, the Duke Activity Status Index, and the Braunwald classification.

B. Physical findings. For patients with a history of chest pain, physical examination helps identify risk factors for CAD and occult cardiac abnormalities.

1. **The signs associated with a high risk for CAD** include elevated blood pressure or manifestations of hypertensive vascular disease such as retinal arteriopathy, signs of hyperlipidemic conditions including corneal arcus or xanthelasma, and evidence of carotid or other peripheral vascular disease.

TABLE 6.1 Classification of Angina

CCS class	Definition	Comment
I	Ordinary physical activity does not cause angina	Angina only with extraordinary exertion at work or recreation
II	Slight limitation of ordinary activity	Angina with walking more than two blocks on a level surface or climbing more than one flight of stairs at a normal pace
III	Marked limitation of ordinary physical activity	Walking one to two blocks on a level surface or climbing one flight of stairs at a normal pace
IV	Inability to carry on any activity without discomfort	Angina at rest or with minimal activity or stress

CCS, Canadian Cardiovascular Society.

2. **Physical examination** performed during an episode of chest pain may reveal rales, an S_3 or S_4 gallop, or a systolic murmur from ischemic mitral regurgitation, all of which generally disappear with resolution of symptoms.

C. **Baseline electrocardiogram (ECG)**

1. A baseline ECG is **useful for the initial screening** of CAD, although about 60% of patients with chest pain have a normal ECG. Presence of a Q wave or persistent ST depression is associated with an unfavorable outcome. The ECG can also demonstrate other abnormalities, such as left ventricular (LV) hypertrophy, bundle branch block, and preexcitation syndromes.
2. Information obtained from the ECG is **useful in the assessment of chest pain** and helps to stratify patients who are at risk for an adverse event.
3. ECG at the time of chest pain can also **help identify the cause of the chest pain**. Transient changes in the T-wave, ST-segment, or conduction patterns point toward a cardiac source of the chest pain. A normal ECG does not exclude ischemia as being the etiology of chest pain.

III. DIAGNOSTIC TESTING. For a patient with stable CAD, investigations are aimed at risk stratification and management of symptoms and unfavorable outcomes.

A. Stress testing. The basic principle of stress testing is to provoke ischemia or produce coronary vasodilation, followed by functional assessment with different systems to detect ischemia. Stress tests can be categorized according to the methods used to provoke and detect myocardial ischemia. The sensitivity and specificity of each test to identify coronary stenosis vary according to the study population, definition of disease, definition of a positive test result, protocol used for the stress testing, and experience of the interpreter. The following is a brief overview of noninvasive cardiac testing. **For a thorough discussion on noninvasive imaging and stress modalities, please refer to the specific chapters**.

1. **Methods to induce ischemia.** Exercise is the most physiologically sound and useful method for inducing ischemia. An exercise test is considered adequate if 85% or more of age-predicted maximum heart rate (220 – age) is achieved. Exercise testing provides an objective assessment of functional capacity, which provides useful prognostic information. Pharmacologic testing, with dobutamine or adenosine/adenosine derivatives (i.e., dipyridamole), can be used for patients who cannot exercise adequately.

2. **Methods to assess ischemia**
   a. **Stress ECG.** Exercise ECG provides useful diagnostic information about the patients with normal baseline ECGs who are at intermediate risk for CAD. Stress ECG is also used to create an exercise prescription in patients with stable angina. The sensitivity and specificity of stress ECG are poor among patients with an abnormal baseline ECG, LV hypertrophy, ventricular pacing, left bundle branch block (LBBB), or intraventricular conduction disturbance and among patients taking digitalis or other medications that affect conduction and depolarization. Electrocardiographic changes during dipyridamole or adenosine infusion have high specificity but poor sensitivity. Electrocardiographic changes during dobutamine infusion have sensitivity and specificity similar to those of exercise ECG.
   b. **Echocardiographic imaging.** Stress echocardiography is an economical test with good specificity for identifying the location and extent of ischemic territories. This is assessed by the induction of regional wall motion abnormalities with stress or dilation of the left LV cavity with stress (which may indicate global ischemia). If the patient is unable to exercise, a dobutamine stress test can be performed. A biphasic response with dobutamine, in which contractility initially increases with lower doses of dobutamine and then decreases with higher doses, is diagnostic of ischemia. Augmentation of contractility in hypokinetic segments may indicate the presence of hibernating myocardium in a specific coronary distribution. At some medical centers, dipyridamole and adenosine stress tests are performed with echocardiographic imaging. This method is less sensitive in detecting underlying CAD. Results of stress echocardiography are difficult to interpret in some patients with a hypertensive response to exercise and in some patients with severe mitral or aortic regurgitation. Preexisting wall motion abnormalities may further complicate image interpretation.
   c. **Radionuclide imaging.** Single-positron emission computed tomography (SPECT) can be performed after injection with thallium 201 or technetium (Tc) 99m–labeled radiopharmaceuticals. Positron emission tomography (PET) can be performed utilizing rubidium 82 or 13N ammonia tracers. PET imaging provides greater spatial resolution and diagnostic accuracy in comparison with SPECT imaging. Injection of fluorine 18–labeled deoxyglucose (FDG) allows assessment of myocardial viability in patients with resting perfusion defects. The sensitivity and specificity of nuclear testing are decreased among patients with severe obesity, balanced three-vessel disease, and LBBB.

B. **Echocardiography** provides useful information in the overall assessment of suspected stable angina.
   1. Regional wall motion abnormalities involving the left ventricle are commonly caused by CAD and may represent resting ischemia or prior MI. Any impairment in LV systolic function, LV hypertrophy, and presence of substantial mitral regurgitation are associated with heightened clinical risk and poor outcome. LV systolic function may guide the choice of medical therapy versus revascularization.
   2. Echocardiography is the test of choice to quantify aortic stenosis or the presence of hypertrophic cardiomyopathy.

C. **Magnetic resonance imaging (MRI)**
   1. Ischemic evaluation using pharmacologic stress (dobutamine or adenosine) and cardiovascular magnetic resonance can also be utilized to evaluate myocardium in jeopardy. MRI uses gadolinium as a contrast medium to evaluate regional wall motion abnormalities and ejection fraction, as well as segmental myocardial perfusion (when using adenosine). MRI can also provide direct visualization of the

coronary arteries, although computed tomography (CT) angiography is much better for this application.

2. Delayed-phase gadolinium imaging also provides information on the location and transmurality of myocardial scar.
3. The weaknesses include increased cost, lack of portability, and unsuitability for use in the growing population of patients with pacemakers and defibrillators.

D. Electron beam computed tomography (EBCT)

1. EBCT is a noninvasive method of obtaining cross-sectional images of the heart and allows quantification of coronary artery calcification. The test is rapid and provides a "calcium score." This test does not provide sufficient detail to accurately quantify and grade stenosis due to atherosclerotic lesions. An increasing calcium score correlates strongly with heightened risk of cardiovascular events and abnormal findings should lead to further risk factor modification and cardiovascular risk assessment.

E. Multidetector computed tomography

1. **Strengths.** Coronary computed tomography angiography (CCTA) allows for the evaluation of the epicardial coronary tree using a noninvasive approach. The sensitivity of CCTA for assessing coronary stenosis approaches 97% with a specificity of 86% when using a 64-slice technology. With technologic advances allowing a greater number of slices to be acquired in current practice, the accuracy of this study is expected to increase. Importantly, the negative predictive value of CCTA is 99%, with an optimal study and appropriate patient selection. Severe coronary artery calcification or previous coronary stent placement may significantly detract from image quality, rendering the evaluation of specific coronary segments uninterpretable. Larger stents may be grossly evaluated for patency but accurate quantification for in-stent restenosis in anatomical locations distal to the left main coronary artery (LMCA) is not always feasible.

F. Coronary angiography

1. **Strengths.** Coronary angiography is the standard for anatomic assessment of coronary arterial stenosis and provides important prognostic information.
   a. Patients with > 75% stenosis involving at least one coronary artery have a lower survival rate than patients with 25% to 50% or < 25% stenosis. Even for mild stenosis, risk for MI is markedly higher than for no stenosis.
   b. The severity of lesions demonstrated with angiography is not predictive of plaque stability; two-thirds of patients with acute MI have stenosis of > 50% diameter at the site of plaque rupture before MI. It is possible, however, to assess plaque instability on the basis of angiographic characteristics or morphologic features of the lesion.
      (1) Eccentric lesions with narrow necks, overhanging edges, or scalloped borders (type II plaques) are more unstable than concentric lesions with smooth borders (type I plaques).
      (2) Lesion roughness (i.e., irregular borders) is predictive of plaque instability and heightens the risk of future infarction.
      (3) The morphologic characteristics of the plaque help in judging the feasibility and risk of percutaneous or surgical intervention.
   c. Ventriculography performed at the time of selective coronary angiography adds an important dimension to risk stratification by providing an index of LV systolic function and regional wall motion characteristics as well as the presence and degree of mitral regurgitation.
2. **Indications.** In the management of stable angina, use of angiography is variable. An American College of Cardiology and American Heart Association (ACC/AHA) task force classified the indications for coronary angiography into three categories. The relevant indications in the context of stable angina are presented in Table 6.2.

TABLE 6.2 Indications for Coronary Angiography in Stable Angina

Class I (general agreement among cardiologists)
Severe anginal symptoms (CCS class III or IV) with optimal medical therapy
Stress testing indicators of high-risk coronary disease
Survivors of sudden cardiac arrest
Symptoms of congestive heart failure with angina
Clinical predictors of severe CAD
Class II (frequently used but controversial)
Symptoms of angina and positive stress test
Inadequate information from noninvasive testing
Severe angina that improves to mild/moderate angina with medical therapy
Anginal symptoms and intolerance of medical therapy
Asymptomatic patients with positive stress test
Patients who are unable to be evaluated noninvasively
Patients with an occupation that involves an unusual degree of risk
Patients suspected of ischemic symptoms caused by nonatherosclerotic coronary disease (i.e., vasculitis and radiation coronary disease)
Suspicion of coronary vasospasm with the need for provocative testing
Suspicion of left main or three-vessel coronary disease
Recurrent hospitalization for chest pain and need for definitive coronary evaluation
Patients with intermediate or high probability of CAD and a desire for definitive diagnosis
Class III (unjustified use of angiography)
Mild symptoms that resolve with medical therapy
Patients who would not undergo revascularization
Patients with low probability of CAD and a desire for definitive diagnosis

CAD, coronary artery disease; CCS, Canadian Cardiovascular Society.

3. **Limitations.** Coronary angiography underestimates plaque burden, possibly because of vascular remodeling and the diffuse nature of the disease. Coronary angiography does not depict intraluminal plaque burden and does not show coronary flow reserve. Adjunctive use of intravascular ultrasonography (IVUS) greatly facilitates the investigation of hazy areas on coronary angiograms, which may be caused by calcium, thrombus, severe eccentric lesion, or dissection. The IVUS can also assess positive and negative remodeling, which has been shown to correlate with stable and unstable syndromes.

G. Intravascular ultrasonography allows visualization of the cross-sectional image of coronary arteries. This modality helps to quantitate plaque area, artery size, and luminal stenosis; assess hazy areas on coronary angiograms, questionable areas of stenosis, and extent of stenosis; and sometimes determine the calcium content of a plaque. Hypodense areas in a plaque may correlate with high lipid content, which may indicate fast-growing or potentially unstable plaque. This information can help

assess the need for and options of therapy. This modality does not, however, have a role in routine evaluation of patients with stable angina, due to the invasive nature of the test.

H. Optical coherence tomography (OCT) is a relatively new intracoronary imaging modality that has better resolution than IVUS but provides less depth. It has been used, thus far, almost exclusively as a research tool, but a number of studies are currently ongoing to establish its clinical utility. Potential contributions of OCT include characterization of plaque, better understanding of stent characteristics (degree of apposition and stent endothelialization, etc.), and arterial remodeling. This technique requires injection of contrast medium during imaging (usually totaling 12 to 20 cc per run) and so may be of limited use in patients with chronic kidney disease.

I. Invasive functional assessment. Invasive assessment of the functional significance of an intermediate stenosis can be made by means of coronary blood flow measurement with intracoronary Doppler ultrasound and direct measurement of a pressure gradient across a stenosis.

1. With the help of a small transducer mounted on a guidewire, coronary blood flow can be measured by means of a fixed sample volume and pulsed Doppler.
   - **a.** In the left coronary artery, most coronary flow occurs during diastole. In normal arteries, a ratio of proximal-to-distal flow velocity approaching 1 is considered normal. In the presence of coronary stenosis, coronary blood flow becomes mainly systolic because the diastolic component of the flow is jeopardized first.
   - **b.** Three indices can help identify physiologically important stenoses:
     - **(1)** Diastolic-to-systolic average peak coronary flow velocity ratio of < 1.8 distal to the obstruction
     - **(2)** A proximal-to-distal average peak coronary flow velocity ratio of > 1.7
     - **(3)** Coronary flow reserve (i.e., increase in coronary flow with adenosine, which is administered after intracoronary nitroglycerin) with a less than twofold increase in peak velocity
2. **Direct measurement of pressure gradients** can be accomplished with a transducer mounted on a catheter. Ratio of mean pressure distal and proximal to the lesion after maximum vasodilation (fraction flow reserve or FFR) of < 0.75 to 0.80 indicates a hemodynamically significant lesion. These techniques supplement angiography in determining the functional significance of an intermediate (30% to 70%) angiographic stenosis. In a group of patients with angiographically intermediate stenosis, the Fractional Flow Reserve versus Angiography for Multivessel Evaluation (FAME) investigators were able to demonstrate lower rates of mortality and MI (8.4% vs. 23.9%, $p = 0.02$) with less stent placement when a strategy of FFR-guided (vs. angiography-guided alone) percutaneous coronary intervention (PCI) was pursued.

J. Holter monitoring

1. After MI, increased ventricular ectopy is predictive of increased cardiovascular morbidity and mortality. This association is less important among patients with stable angina without prior MI, and routine Holter testing for risk stratification is not indicated. No medical treatment aimed at suppressing ventricular ectopy has been shown to improve outcome.

IV. THERAPY.

The goals of therapy are to prevent cardiovascular morbidity and mortality and to improve quality of life.

A. Therapeutic options. Medical therapy, PCI, and coronary artery bypass grafting (CABG) have all been shown to control symptoms and improve exercise time to ischemia. In an era of rudimentary medical therapy, CABG has been proven to decrease cardiovascular mortality in specific patient subsets. Although PCI has been shown to improve stable anginal symptoms and improve quality of life, a decrease in mortality has not been proven in randomized controlled trials (RCTs).

B. Pharmacologic therapy

1. Platelet inhibitors

a. The Antiplatelet Trialists' Collaboration was a meta-analysis that included approximately 100,000 patients from 174 trials involving antiplatelet therapy. This data set showed that aspirin (acetylsalicylic acid, ASA) reduced the rate of stroke, MI, and death among high-risk patients, including those with stable angina without previous MI. A recent systematic review confirms that, while optimal dosing is controversial, there is general support in the literature for limiting the dose of ASA to 75 to 81 mg daily. Approximately 5% to 10% of patients with CAD have aspirin resistance, defined as a lack of decrease in platelet function associated with aspirin use. Aspirin resistance has been shown to result in higher thrombotic events in people with peripheral vascular disease. Patients who demonstrate increased platelet reactivity despite aspirin therapy have increased risks for stroke, MI, and vascular death compared with aspirin responders.

b. Among patients with true allergy or intolerance to aspirin, clopidogrel has been shown to decrease the frequency of fatal and nonfatal vascular events in peripheral, cerebral, and coronary vessel diseases.

(1) Clopidogrel is a second-line therapy in patients unable to tolerate aspirin. In high-risk patients with prior cardiac surgery or ischemic events, the use of clopidogrel as monotherapy, or in addition to aspirin, is beneficial. In patients receiving bare-metal stenting (BMS) for stable coronary disease, at least 1 month of dual antiplatelet therapy (DAPT; aspirin 81 mg plus clopidogrel 75 mg daily) is recommended. The use and duration of DAPT with clopidogrel and aspirin in the setting of drug-eluting stent (DES) implantation are currently under intense review, with concerns of very late stent thrombosis (ST) on one hand and studies questioning the benefit of extended duration DAP on the other. The most recent ACC/AHA PCI guidelines recommend 12 months of DAPT in patients undergoing DES, though longer duration may be considered (class IIb) in specific high-risk patient/stent subsets. Clopidogrel is usually well tolerated and has few side effects.

(2) In the initial analysis of the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial, performed on a large group of patients included with either prior cardiovascular events or multiple cardiovascular risk factors, there was no benefit from the use of DAPT over aspirin alone in preventing MI or death. A prespecified analysis of higher risk patients only (such as those with prior MI) did show a decrease in cardiovascular events for the group receiving clopidogrel in addition to aspirin. This suggests that an appropriate group of patients may benefit from prolonged DAPT.

2. Lipid-lowering agents. Among patients with established CAD, secondary prevention with lipid-lowering therapy, specifically statins, has demonstrated marked reduction in risk for subsequent cardiovascular events. Statins are potent inhibitors of 3-hydroxy-3-methylglutaryl coenzyme reductase (HMG-CoA reductase). They are the most effective medical therapy for lowering levels of low-density lipoprotein (LDL) and have also been shown to upregulate nitric oxide (NO) synthase, decrease expression of endothelin-1 mRNA, improve platelet function, and decrease production of detrimental free radicals; all of these promote normal endothelial function.

a. Indications. The Scandinavian Simvastatin Survival Study (4S), Cholesterol and Recurrent Events (CARE), Long-term Intervention with Pravastatin in Ischemic Disease (LIPID), and Heart Protection Study (HPS) trials have provided convincing evidence that in patients with evidence of cardiovascular

disease with normal or elevated cholesterol levels, statins decrease mortality, the rate of MI and stroke, and the need for CABG.

b. Effectiveness. Recent studies have shown that in patients with stable CAD (treating to new targets [TNT]) or post-acute coronary syndrome (ACS) (PROVE IT-TIMI-22), aggressive lipid lowering to an LDL goal of 70 mg/dL decreases the risks of cardiovascular death, MI, and stroke compared with patients treated to an LDL goal of 100 mg/dL. There is also a suggestion that aggressive statin therapy retards and even results in a mild degree of plaque regression as measured by IVUS.

c. Choice of agents. Statins should be the first line of therapy in patients with CAD. The quantification of lipoprotein(a) [Lp(a)], fibrinogen, apolipoprotein (apo A), and apolipoprotein B_{100} (apo B_{100}) is investigational. Bile acid sequestrants primarily reduce LDL cholesterol and should not be used in patients with triglyceride levels higher than 300 mg/dL, because these agents may exacerbate hypertriglyceridemia. Nicotinic acid reduces LDL and triglyceride levels and is the most effective of the available lipid-lowering medications at increasing high-density lipoprotein (HDL) level. It is also the only agent that lowers Lp(a). Fibric acid derivatives are most effective against hypertriglyceridemia; they raise HDL level modestly and have little effect on LDL. They are the first line of treatment in patients with triglyceride levels higher than 400 mg/dL. ω-3 Fatty acids may also be used to treat hypertriglyceridemia that is refractory to niacin and fibric acid therapy. Agents to raise HDL cholesterol, cholesteryl ester transfer protein inhibitors, are currently undergoing intensive clinical evaluation in RCTs and may provide a beneficial treatment adjunct to statin therapy in the future.

(1) Current evidence supports aggressive lowering of LDL cholesterol levels in patients with established coronary disease, or CAD equivalents, to a goal of 70 mg/dL (class IIa). A level of HDL cholesterol > 45 mg/dL and triglycerides < 150 mg/dL are secondary goals of dietary, lifestyle, and pharmacologic therapies.

(2) The side effects of statin therapy, including myositis and hepatitis, are quite rare. The package inserts recommend liver function test evaluation prior to initiation of therapy (or increase in dose) and 3 months thereafter. Blood tests are not necessary for routine follow-up of patients who are stable on these medications and should only be measured based upon clinical suspicion of an untoward effect.

3. Nitrates (Table 6.3)

a. Mechanism of action. Nitrates decrease cardiac workload and oxygen demand by means of reducing preload and afterload of the left ventricle. They also redistribute blood flow to the ischemic subendocardium by means of decreasing LV end-diastolic pressure, vasodilation of epicardial vessels, and improvement of collateral blood flow to ischemic tissue. In an adjuvant role, nitrates may also be weak inhibitors of platelet aggregation.

b. Evidence for effectiveness. Nitrates can decrease exercise-induced myocardial ischemia, alleviate symptoms, and increase exercise tolerance in patients with stable angina.

(1) Adding nitrates to an optimal β-blocker regimen does not improve frequency of anginal episodes, glyceryl trinitrate consumption, exercise duration, or duration of silent ischemia.

(2) In some small studies, the efficacy of nitrates in reducing anginal episodes was increased with concomitant use of angiotensin-converting enzyme (ACE) inhibitors.

(3) No study has shown survival benefit with the use of nitrates to treat patients with chronic stable angina.

TABLE 6.3 Nitrates

Medication	Route of administration	Each dose	Frequency
Nitroglycerin (glyceryl trinitrate, Nitro-Bid, Nitrostat, and Nitro-Dur)	Sublingual tablet	0.15–0.6 mg	As needed
	Sublingual spray	0.4 mg	As needed
	Sustained-release capsule	2.5–9.0 mg	Every 6–12 h
	Ointment (topical)	0.5–2″ (1.25–5 cm)	Every 4–8 h
	Disk (patch)	1 disk (2.5–15 mg)	Every 24 h
	Intravenous	5–400 μg/min	Continuous
	Buccal tablet	1 mg	Every 3–5 h
Isosorbide dinitrate (Isordil, Sorbitrate, and Dilatrate SR)	Sublingual tablet	2.5–10 mg	Every 2–3 h
	Chewable tablet	5–10 mg	Every 2–3 h
	Oral tablet	10–40 mg	Every 6 h
	Sustained-release tablet	40–80 mg	Every 8–12 h
Isosorbide-5-mononitrate (Imdur and Ismo)	Sublingual tablet	10–40 mg	Every 12 h
	Sustained release	60 mg	Every 24 h
Erythrityl tetranitrate (Cardilate)	Sublingual tablet	5–10 mg	As needed
	Tablet	10 mg	Every 8 h

c. Selection of preparations. Because nitrates have a fast onset of action, a sublingual tablet or oral spray offers immediate relief of an anginal episode.

(1) For short-term prophylaxis (up to 30 minutes), nitroglycerin tablets can be used when activities known to precipitate angina are anticipated. Timing and frequency of the doses can be individualized according to the diurnal rhythm of anginal episodes. A nitrate-free interval of about 8 hours is adequate for preventing tolerance.

(2) Use of long-acting medications and transcutaneous delivery systems improves compliance but still necessitates a nitrate-free interval.

d. Side effects. Oral nitrates should be taken with meals to prevent heartburn.

(1) Headache is common and can be severe. Severity usually decreases with continued use and often can be controlled by decreasing the dose.

(2) Transient episodes of flushing, dizziness, weakness, and postural hypotension can occur, but these effects are usually abrogated by positioning and by other procedures that facilitate venous return.

e. Drug interactions

(1) Hypotension can occur with the use of other vasodilators, such as ACE inhibitors, hydralazine, or calcium channel blockers. **Concurrent use of PDE5 inhibitors like sildenafil (Viagra) and nitrates can lead to severe hypotension and, therefore, is *absolutely contraindicated*.**

f. Controversies

(1) Tolerance. Sustained therapy attenuates the vascular and antiplatelet effects of nitrates. Although the basis for this phenomenon of nitrate tolerance is not completely understood, sulfhydryl depletion, neurohormonal activation, and increased plasma volume are likely involved.

Administration of *N*-acetylcysteine, ACE inhibitors, or diuretics does not consistently prevent nitrate tolerance. Intermittent nitrate therapy is the only way to avoid nitrate tolerance.

(2) **Rebound.** Intermittent use of nitrates is not associated with serious rebound of angina among patients taking maintenance therapy with β-blockers. Dosing to allow for a longer nitrate-free interval is also not associated with rebound.

4. **β-Blockers** (Table 6.4)
   a. **Mechanism of action.** Blocking the β_1-adrenergic receptors in the heart decreases the rate–pressure product and oxygen demand. Decreased tension in the LV wall allows favorable redistribution of blood flow from the epicardium to the endocardium.
      (1) Coronary vasospasm is rare from the β_2-receptor blocking effect, but use of β-blockers should be avoided among patients with known, active vasospasm.
      (2) β-Blockers have a variable degree of membrane-stabilizing effect.
   b. **Evidence for effectiveness.** β-Blockers decrease mortality after MI. The mortality benefit is not proven among patients with stable angina without prior MI, although symptomatic improvement is well documented.
   c. **Side effects.** The most important side effects are related to blockade of β_2-receptors. However, data show that some of the side effects may occur less frequently than previously believed, and potentially lifesaving therapy should be offered to those at greatest risk for adverse events.
      (1) Bronchoconstriction, masking of symptoms caused by hypoglycemic reaction among patients with diabetes, exacerbation of symptoms of peripheral vascular disease, and central nervous system (CNS) side effects such as somnolence, lethargy, depression, and vivid dreaming are well documented. The CNS side effects are thought to be related to the lipid solubility of these compounds.
      (2) Symptomatic bradycardia and precipitation of heart failure are concerns for patients with a diseased conduction system and preexisting heart failure, respectively.
      (3) Decreased libido, impotence, and reversible alopecia can be a problem for some patients.
      (4) β-Blockers adversely alter lipid profile by increasing LDL cholesterol and decreasing HDL cholesterol.
   d. **Drug interactions.** Severe bradycardia and hypotension can occur with concomitant use of some calcium channel blockers.
   e. **Selection of preparations.** Cardioselectivity, lipid solubility, mode of excretion, and frequency of dosing are the main considerations when selecting a particular agent. The major cardiospecific agents (i.e., β1 blockade) include metoprolol, atenolol, bisoprolol, and nebivolol. Of note, nebivolol also induces the endothelial NO pathway and contributes to vasodilation. Intrinsic sympathomimetic activity is not a clinically important factor in the choice of a medication, although benefits in patients with CAD have been decreased with agents having intrinsic sympathomimetic activity.
   f. **Effect on lipids.** The clinical significance of lipid abnormalities associated with β-blockers is unclear. β-Blockers have been associated with a decline in HDL level and a rise in triglycerides level. β-Blockers can improve survival among patients in New York Heart Association (NYHA) class I or II heart failure and angina. The condition of a patient with NYHA class III or IV disease should be stabilized before β-blocker therapy is instituted.
5. **Calcium channel blockers** (Table 6.5)

TABLE 6.4 β-Blockers

Compound	Daily dose (mg)	Frequency	Excretion	Lipid solubility	Intrinsic sympathomimetic activity	Membrane stabilization
Selective β-blockers						
Metoprolol						
Short-acting	50–400	Every 12 h	Liver	Moderate		
Long-acting		Every 24 h			None	Possible
Atenolol	25–200	Every 24 h	Kidney	None	None	None
Acebutolol	200–600	Every 12 h	Kidney	Moderate	Low	Low
Nebivolol	5–40	Every 24 h	Kidney	High	None	
Betaxolol	20–40	Every 24 h	Kidney		Low	
Nonselective β ($\beta_1 + \beta_2$)-blockers						
Propranolol	80–320	Every 4–6 h	Liver			
Long-acting		Every 12 h		High	None	Moderate
Nadolol	80–240	Every 24 h	Kidney	Low	None	None
Timolol	15–45	Every 12 h	Liver	Moderate	None	None
Pindolol	15–45	Every 8–12 h	Kidney	Moderate	Moderate	Possible
Labetalol[a]	600–2,400	Every 6–8 h	Liver	None	None	Possible
Carvedilol[a]						
Short-acting	25–50	Every 12 h	Liver	Moderate	None	Possible
Long-acting	10–80	Every 24 h				

[a]Also a potent α_1-antagonist.

TABLE 6.5 Calcium Channel Blockers

Compound	Each dose (mg)	Frequency	Vasodilation	Sinoatrial node inhibition	Atrioventricular node inhibition	Negative inotrope
Nifedipine	30–120	Every 8 h	5	1	0	1
Nifedipine (Procardia XL)	30–180	Every 24 h				
Diltiazem	30–90	Every 6–8 h	3	5	4	2
Diltiazem (Cardizem CD)	120–300	Every 24 h				
Verapamil	40–120	Every 6–8 h	4	5	5	4
Verapamil (Calan SR and Isoptin SR)	120–240	Every 12 h				
Amlodipine (Norvasc)	2.5–10	Every 24 h	4	1	0	1
Felodipine (Plendil)	5–20	Every 24 h	5	1	0	0
Bepridil (Vascor)	200–400	Every 24 h	4	4	4	5
Isradipine (DynaCirc)	2.5–10	Every 24 h	4	4	0	0
Nicardipine (Cardene)	10–20	Every 8 h	5	1	0	0

0, no activity; 5, most potent effect. Intermediate numbers suggest intermediate potency of effects.

a. **Mechanism of action.** These agents block calcium entry into vascular smooth muscle cells and cardiac cells by inhibiting calcium channels, but they do not affect the regulation of intracellular calcium release. The result is decreased contraction of muscle cells.
   (1) The four types of calcium channels are L, T, N, and P.
   (2) The T-type calcium channels are located in the atria and sinoatrial node and affect the phase I of depolarization.
   (3) The L-type channels contribute to entrance of calcium into the cell during phase III of the action potential.
   (4) The N and P types of channels are present mainly in the nervous system.
   (5) The three main groups of calcium channel blockers are dihydropyridines (e.g., nifedipine), benzothiazepines (e.g., diltiazem), and phenylalkylamines (e.g., verapamil).
   (6) The dihydropyridines bind to the extracellular portion of the L channels at a specific site. They do not bind to the T channels and do not have a negative chronotropic effect. Because of their extracellular site of action, dihydropyridines do not inhibit receptor-induced intracellular calcium release.
   (7) Verapamil binds to the intracellular part of the L channel and inhibits the T channel. Intracellular calcium release is inhibited by verapamil because of its intracellular binding site and reflex sympathetic activation is less effective. Use dependence occurs with verapamil because open channels are needed for transport of the drug into the intracellular binding site. In stable angina, verapamil helps by improving rate–pressure product and by increasing oxygen delivery from coronary vasodilation.

b. **Evidence of effectiveness.** Numerous placebo-controlled, double-blind trials have shown that calcium channel blockers decrease the number of anginal attacks and attenuate exercise-induced depression of ST segments.
   (1) Studies comparing the efficacy of β-blockers and calcium channel blockers in the management of stable angina in which death, infarction, and unstable angina were used as end points showed calcium channel blockers to be as effective as β-blockers.
   (2) Increased mortality caused by short-acting nifedipine among patients with CAD was demonstrated in a retrospective study and meta-analysis. If the use of nifedipine is contemplated, a long-acting preparation in conjunction with β-blocker therapy is the safer approach. The mechanism of increased mortality is unclear, but reflex tachycardia and coronary steal phenomenon are potential explanations.

c. **Side effects.** The most common side effects are hypotension, flushing, dizziness, and headache. Because a negative inotropic effect can precipitate heart failure, the use of calcium channel blockers to treat patients with impaired LV function is relatively contraindicated. Conduction disturbances and symptomatic bradycardia occur with the use of compounds that have a marked inhibitory effect on the sinoatrial and atrioventricular nodes. Bepridil is known to prolong QTc, and QT monitoring is necessary when this medication is used. Lower extremity edema is often seen with the use of dihydropyridine calcium channel blockers and this may necessitate lowering the dose or discontinuation of the medication. The non–dihydropyridine calcium channel blockers are also known to cause constipation.

d. **Drug interactions.** Digitalis levels are increased by the non–dihydropyridine calcium channel blockers verapamil and diltiazem. The use of these drugs is contraindicated in the presence of digitalis toxicity.

e. **Selection of preparations.** Calcium channel blockers have a variable negative inotropic effect.

(1) Amlodipine is most likely to be tolerated by patients with compensated heart failure. In decompensated heart failure, all calcium channel blockers should be avoided. Amlodipine is the only calcium channel blocker approved for angina by the US Food and Drug Administration (FDA).

(2) Patients with conduction disturbances should take agents with minimal effects on the conduction system. Longer acting preparations minimize the risk for precipitation of angina caused by reflex tachycardia.

6. **ACE inhibitors.** The rationale for using ACE inhibitors to manage chronic stable angina comes from post-MI and heart failure trials that demonstrated a significant reduction in ischemic events with the use of ACE inhibitors.
   a. It is possible that ACE inhibitors, by decreasing mainly the preload and, to some extent, afterload, decrease myocardial oxygen demand and help in the management of chronic stable angina. The Heart Outcomes Prevention Evaluation (HOPE) trial in high-risk patients with CAD, stroke, diabetes, and peripheral vascular disease showed that ramipril was associated with a significant reduction in death, MI, and stroke in this population. A recent meta-analysis found that ACE inhibitors reduce the risk of these outcomes even in patients with atherosclerosis who do not have evidence of systolic dysfunction. It is notable that the randomized Prevention of Events with Angiotensin-Converting Enzyme Inhibition (PEACE) study evaluating the use of trandolapril in patients with preserved LV function did not find a benefit with respect to death, MI, angina, revascularization, or stroke. Numerous hypotheses to explain these divergent results, including dose effects, difference in medication effects, and the risk level of enrolled patients, have been postulated. Nevertheless, the use of ACE inhibitors is recommended (class I) for patients with abnormal LV function and considered reasonable (class IIa) for patients with normal LV function.
   b. The relative efficacy of different ACE inhibitors for relieving ischemia has not been well studied.
   c. Serious side effects of ACE inhibitors include cough, hyperkalemia, and decreased glomerular filtration rate. They are contraindicated in the care of patients with hereditary angioedema or bilateral renal artery stenosis.
7. **Hormone replacement therapy (HRT).** The lipid profiles of women change unfavorably after menopause. LDL, total cholesterol, and triglyceride levels increase and HDL level decreases. All these changes have an adverse effect on cardiovascular morbidity and mortality. Several large case-controlled and prospective cohort studies suggested that the postmenopausal use of estrogen alone or in combination with medroxyprogesterone acetate has a favorable effect on lipid profile and cardiovascular events. However, both the Women's Health Initiative (WHI) study on primary prevention and the Heart and Estrogen/progestin Replacement Study (HERS) on secondary prevention showed an increased risk of cardiovascular and cerebrovascular events in postmenopausal women receiving HRT. Another randomized trial quantifying coronary atherosclerosis angiographically showed negative results with respect to estrogen use. As a result, it has been postulated that the previously shown benefits might have been caused by the "healthy user" effect, and the use of HRT for primary prophylaxis against cardiovascular events is not recommended.
   a. **Benefits of use.** Although the use of estrogen has shown an increase in cardiovascular events, it is associated with some specific favorable findings. The positive effects of estrogen use include maintenance of normal endothelial function, reduction in levels of oxidized LDL, alteration in vascular tone, maintenance of normal hemostatic profile, a favorable effect on plasma glucose levels, reduction of osteoporotic fractures, and a reduction in menopausal symptoms.

b. **Side effects** include bleeding, nausea, and water retention. Because doses of estrogen are small, these side effects are uncommon. For patients with an intact uterus, routine gynecologic examination is mandatory for cancer surveillance. The risk of breast cancer is also increased with the use of HRT, and routine screening is beneficial.

8. **Antioxidants.** The role of vitamins A, C, and E is unclear in patients with CAD.
   a. The initial observational studies on the role of daily vitamin E supplementation in reducing the risk of cardiovascular events among patients with proven atherosclerotic heart disease appeared promising. However, when vitamin E was tested in a randomized fashion, no benefit in its use was proved. There are also data suggesting that vitamin E may attenuate the effect of statins. Vitamins A, C, and E are not recommended for the secondary prevention of cardiovascular events.
   b. Data are lacking about vitamins A and C. Most of the available information suggests no benefit in taking supranormal doses of these vitamins. Vitamin A does not prevent LDL oxidation, even though it binds to LDL molecules. Because it is water soluble, vitamin C does not bind to the LDL molecule. These two vitamins are not recommended for the prevention of progression of atherosclerosis.
9. **Ranolazine**
   a. Ranolazine has recently been shown to work by inhibiting the late sodium channel in myocytes, which can otherwise remain open in pathologic states such as ischemia and heart failure. By reducing the late sodium entry into myocytes, ranolazine causes reduced sodium-dependent calcium entry into the cytosol. This downstream reduction in intracellular calcium levels is thought to reduce diastolic stiffness, thereby improving diastolic blood flow and reducing ischemia and angina. Earlier studies had suggested that effects of ranolazine were primarily through its impact on fatty acid metabolism; however, the weight of evidence now suggests that late sodium channel inhibition is its primary mechanism.
   b. Numerous randomized studies of ranolazine, with or without background antianginal therapy, have shown a benefit in patients with stable angina with respect to frequency of anginal attacks, exercise duration, time to ST-segment depression on treadmill testing, and use of sublingual nitroglycerin.
   c. **Side effects.** Dizziness, headache, and GI intolerance are the most common side effects noted. Prolongation of the QT interval has been reported, especially in patients with hepatic or liver dysfunction due to decreased metabolism. **Prolonged QT interval** at baseline or during treatment follow-up **is a contraindication** to its use.
   d. **Drug interactions.** Inhibitors of CYP3A4, such as azole antifungals, non–dihydropyridine calcium channel blockers, macrolide antibiotics, protease inhibitors, and grapefruit juice, should not be used concomitantly due to inhibition of ranolazine metabolism.
10. **Newer pharmacologic approaches**
   a. Therapy with direct infusion of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor proteins has been shown to increase collateral blood flow in animal models. Studies are underway to investigate the role of these agents in improving collateral blood flow to the ischemic myocardium of patients with angina. Although early results are encouraging, long-term risks and benefits of such therapy remain largely unknown.
   b. Approaches involving the use of gene therapy to cause overexpression of these endogenous growth factors to control the development of collateral blood vessels have been proposed. These approaches are under investigation.

11. **Enhanced external counterpulsation (EECP)** has become a treatment option for patients with stable angina.
    a. EECP involves the intermittent compression of the lower extremities in an effort to increase diastolic pressure and augment coronary blood flow. Three sets of balloons are wrapped around the lower legs, lower thighs, and upper thighs, with precise cuff inflation and deflation gated with the ECG. The lower cuffs are inflated at the start of diastole, as represented by the beginning of the T wave, and simultaneous deflation of all three chambers is triggered just before systole at the onset of the P wave.
    b. In patients with refractory angina, clinical trials have demonstrated improvements in exercise tolerance, reduction in anginal symptoms, decreased use of nitroglycerin, and improvements in objective measures of ischemia as measured by thallium scintigraphy. These benefits are maintained at 2 years of follow-up.

C. **Percutaneous coronary intervention.** The effectiveness of PCI to control symptoms in chronic stable angina and to prevent death or MI has been compared with medical management and CABG.
    1. **Compared with medical treatment**
        a. The Angioplasty Compared with Medicine (ACME) trial compared PCI with medical therapy in approximately 200 patients with single-vessel and multivessel CADs. Patients with single-vessel CAD showed better symptomatic relief at 6 months with PCI but no difference in mortality or MI. Patients with two-vessel CAD had no significant differences in symptoms, mortality, or MI.
        b. The Medicine, Angioplasty, or Surgery Study (MASS) randomized approximately 200 patients with proximal left anterior descending (LAD) artery disease to medical therapy, PCI, or CABG. This study demonstrated no difference in the primary end point (i.e., death, MI, or refractory angina necessitating revascularization). Patients randomized to CABG had a lower incidence of events compared with the other two groups, driven by a decrease in repeat revascularization procedures.
        c. The Randomized Intervention Treatment of Angina-2 (RITA-2) trial randomized more than 1,000 patients with stable angina to medical therapy or PCI. After 2.7 years of follow-up, the primary end point (i.e., death or MI) was lower in the medically treated group. There was an improvement in angina, exercise capacity, and perceived quality of life in patients who underwent PCI. There was also a higher incidence of revascularization in the medically treated group.
        d. The study on Optimal Medical Therapy (OMT) with or without PCI for Stable Coronary Disease (by the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation [COURAGE] Trial Research group) evaluated patients with severe angiographic disease of one or more vessels, and either classic symptoms or documented ischemia on provocative testing. Compared with aggressive medical therapy, an initial strategy of PCI with BMS did not reduce the primary endpoint of death or major adverse cardiovascular events including symptom relief. Notable limitations to the interpretation of this study include the fact that the OMT group had stringent follow-up to achieve the high rates of medical adherence, one-thirds of patients in the medical therapy group crossed over to PCI (but were included in the OMT group as intention-to-treat analysis), and almost 80% of patients had no or minimal angina. Furthermore, it should be stressed that all patients were enrolled after angiography had been performed.
        e. In a substudy of patients enrolled in COURAGE on the basis of positive stress imaging, investigators found that PCI in addition to OMT was

superior in reducing ischemia than OMT alone. Furthermore, the degree of residual ischemia was related to future risk of death or MI. The adequately powered ISCHEMIA trial has been funded by the National Heart, Lung, and Blood Institute to address this issue.

f. The Occluded Artery Trial (OAT) tested the hypothesis that routine PCI of totally occluded arteries 3 to 28 days after MI in high-risk but asymptomatic patients would improve outcomes. In the 2,166 patients studied, there was no statistically significant difference in long-term cardiac events between the PCI and the medical therapy groups, although the PCI group had more rapid relief of angina.

g. The use of DES in comparison to BMS has significantly decreased the risk of in-stent restenosis and the need for target vessel revascularization, thereby improving quality of life, providing freedom from angina, and reducing the risk of repeat procedures. Acknowledging the slightly greater risk of ST with DES compared with BMS, the absolute risk of ST even with DES is quite low. Therefore, their use in appropriate situations is still highly considered in patients without bleeding issues, upcoming surgery, or financial constraints to long-term antiplatelet therapy.

2. Compared with CABG

a. The Emory Angioplasty versus Surgery Trial (EAST) randomized approximately 400 patients with multivessel disease to PCI or CABG. After 8 years of follow-up, there was no difference in the combined end point of mortality, Q-wave MI, and large thallium perfusion defect. In patients with proximal LAD artery disease or diabetes, there was a nonsignificant trend toward improved survival with CABG.

b. The Bypass Angioplasty Revascularization Investigators (BARI) conducted the largest trial comparing PCI with CABG in the management of multivessel disease. In this trial, there was no difference in survival between patients randomized to PCI or CABG at 7 years of follow-up, although the subgroup of patients with diabetes had a better survival rate with CABG than with PCI (76.4% vs. 55.7%).

c. The Arterial Revascularization Therapies Study (ARTS) randomized 1,200 patients with multivessel disease to CABG or BMS placement. After 1 and 5 years of follow-up, there was no difference in mortality, MI, or stroke. Outcomes were similar for patients with stable and unstable angina. Among diabetic patients, however, mortality was greater for those who received PCI. There was a greater incidence of repeat revascularization in the PCI group, although the use of DES in ARTS 2 (compared with the historic CABG group from ARTS 1) shows a similar 1-year rate of revascularization between PCI and CABG groups.

d. The surgery or stenting (SoS) study compared almost 1,000 patients with multivessel disease in the setting of ACS or non-ACS presentation. There was an increased mortality and need for repeat revascularization in the PCI group, which could not be attributed to a diabetic population.

e. In the BARI 2 Diabetes (BARI 2D) trial published more recently, investigators compared prompt revascularization (PCI or CABG as deemed appropriate) and OMT in a group of patients with type 2 diabetes mellitus and CAD. The primary outcome of death was not significantly different in the two groups, nor was the rate of major cardiovascular events (the major secondary end point including death, MI, and stroke). When stratified by revascularization strategy, patients in the CABG group had greater freedom from major cardiovascular events (77.6% vs. 69.5%, $p = 0.01$); this finding was not significant in patients undergoing PCI. Notably, however, this trial was not designed to compare CABG and PCI as revascularization strategies.

f. The recently reported SYNergy between PCI with TAXus and cardiac surgery (SYNTAX) was a pivotal trial randomizing patients with three-vessel disease or left main trunk (LMT) stenosis to multivessel PCI versus CABG. The primary end point of death, stroke, MI, and repeat revascularization favored CABG (12.3% vs. 17.6%, $p = 0.002$). The secondary end point which included death, stroke, and MI was not different between the two groups (7.7% vs. 7.6%, $p = 0.98$). The primary end point favoring CABG was therefore driven primarily by increased rates of repeat revascularization in the PCI group (13.5% vs. 5.9%, $p < 0.001$), though notably the rate of stroke was also significantly lower in the PCI group (2.2% vs. 0.6%, $p = 0.003$).

g. The other major take-home point of the SYNTAX trial was the formulation of the SYNTAX score, which received a class I indication for evaluation of LMT or multivessel disease in the most recent ACC/AHA PCI guidelines. The SYNTAX score grades coronary anatomy on the basis of lesion location, complexity, and functional impact and is a helpful tool for assessing patients at the individual level when discussing options of CABG versus PCI. In the trial, outcomes were assessed by SYNTAX score tertile: patients with a low (0 to 22) or intermediate (23 to 32) score had no difference between the two modes of revascularization for the primary outcome. In patients with a score > 32, however, CABG was favored for the primary outcome (10.9% vs. 23.4%, $p < 0.001$).

h. In patients with LMT stenosis, guidelines had long recommended CABG as the treatment of choice. However, in the modern era of stent placement, PCI of "unprotected" LMT stenosis has gained favor. The 2011 ACC/AHA PCI Guidelines revised the previous class III recommendation for unprotected LMT PCI to class IIa.

Small studies have shown that the mortality difference between PCI and CABG in similarly matched groups of patients is negligible. Furthermore, recent studies comparing the experience of DES implantation in LMT with BMS placement have shown a marked decrease in the need for repeat revascularization.

i. In the prespecified subgroup of patients undergoing unprotected LMT PCI versus CABG in the SYNTAX trial, the primary outcome was similar between the two groups. As in the main study population, stroke was higher in the CABG group (2.7 vs. 0.3%, $p = 0.009$) and repeat revascularization was higher in the PCI group (11.8 vs. 6.5%, $p = 0.02$). Given the clinical equipoise that surrounds unprotected LMT revascularization, the EXCEL (Evaluation of Xience Prime versus Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization) trial is currently underway. The investigators plan to randomize 2,500 patients with LMT stenosis and a SYNTAX score < 32 to PCI versus CABG.

j. At present, strong consideration is given to CABG in the group of patients with multivessel disease and diabetes, LV dysfunction, or LMT disease who are able to undergo open heart surgery. In the general population with multivessel or LMT disease, however, there is a paucity of evidence showing a survival advantage to CABG over PCI, and recent trials with modern treatment practices (including DES implantation, aggressive antiplatelet therapy, off-pump coronary artery bypass procedures, and use of arterial grafts) have shown favorable comparisons between the two treatment strategies. For patients who are able to undergo either of the treatments, an educated decision should be made by the patient, the cardiologist, and a cardiac surgeon.

3. Revascularization methods. For details of PCI strategy and equipment, please refer **Chapter 65**.

D. Coronary artery bypass grafting

1. **Compared with medical treatment.** Compared with medical treatment, CABG improves the survival rate among patients with high-risk stable angina. The benefit is most profound in patients with three-vessel CAD, impaired LV function, or substantial LMCA stenosis.
   a. This information is derived from the Coronary Artery Surgery Study (CASS), European Coronary Surgery Study (ECSS), and Veterans Administration Cooperative Study (VACS). These trials were completed before generalized awareness grew regarding the benefits of medical management with β-blockers, ACE inhibitors, antiplatelet agents, or lipid-lowering medications.
   b. Surgical techniques have also changed significantly, with greater use of arterial conduits including internal mammary artery (IMA) grafts, minimally invasive surgery, and improved techniques of cardiac tissue preservation and anesthesia.
2. **Venous or arterial grafts.** There are different techniques of CABG. The use of minimally invasive bypass surgery involving the left internal mammary artery (LIMA) in patients with isolated LAD artery stenosis has not shown any difference in the rate of mortality, MI, or stroke in comparison to PCI but has shown a decrease in the need for repeat revascularization. With open sternotomy, in which the use of LIMA is well studied, mammary arterial grafting has better long-term outcome compared with vein graft conduits. Given the success of the (LIMA) graft, other arterial conduits have been used, such as the right internal mammary artery (RIMA), the radial artery, and the right gastroepiploic artery.
   a. Twenty percent of venous grafts are nonfunctional at 5 years and only 60% to 70% are functional after 10 years. In contrast, > 90% of LIMA to LAD artery grafts are patent 20 years after the operation.
   b. **Internal mammary artery** grafts have a better patency rate at 10 years when used for LAD lesions (95%) than for circumflex (88%) or right coronary artery (76%) lesions. The patency rates are higher for LIMA compared with RIMA and for in situ grafts compared with free grafts.
   c. Patient survival is better with an IMA graft than when only saphenous venous grafts are used. This survival benefit persists for up to 20 years.
   d. The use of bilateral IMA grafts appears promising, with evidence that the use of RIMA in addition to LIMA improves survival in comparison to LIMA plus saphenous vein grafting. The use of RIMA is technically difficult, however, and has, therefore, not been widespread.
   e. The radial artery graft was introduced into clinical practice around the year 1970 and initially had mixed results. However, at approximately 1 year, 92% of the grafts are patent and at 5 years 80% to 85% of grafts are open. The right gastroepiploic arterial graft has been in use for approximately 15 years, and a 5-year angiographic patency rates of 92% has been reported.
3. **Previous CABG.** Little information is available on the treatment of patients who have already undergone bypass surgery and have stable angina. Although another bypass operation may be offered to these patients, direct comparison with medical treatment in this patient population has not been made. The use of multiple arterial grafts at the time of first CABG reduces the need for reoperation.
4. **Compared with PCI.** This is discussed in Section **IV.C**.

E. Other forms of revascularization

Percutaneous and intraoperative transmyocardial revascularization are potential treatments for patients with coronary disease not amenable to PCI or CABG. Some reports suggest improvement in symptoms, a decrease in perfusion defects, and improvement in contractile function after these procedures but no survival benefit

has been reported. This procedure should be reserved as palliation for patients with medically refractory angina and no other revascularization option, but it has generally fallen out of favor in recent years.

Promotion of ancillary blood vessels by means of injection of blood vessel–promoting agents such as VEGF at the time of surgical or percutaneous coronary revascularization is currently under investigation. So far, the results of this form of intervention have been mixed. Smaller studies targeting improvement in perfusion and exercise tolerance suggest some benefit in the active treatment group. However, two, somewhat larger, studies have recently been terminated early due to lack of benefit at interim analysis.

F. Lifestyle modification

1. **Exercise**
   a. **Rationale.** Exercise conditions the skeletal muscles, which decreases total body oxygen consumption for the same amount of workload. Exercise training also lowers heart rate for any level of exertion, which decreases the oxygen demand on the myocardium for any workload. Some evidence shows that higher physical activity and exercise can decrease cardiovascular morbidity and mortality.
   b. **Recommendation.** For secondary prevention, aerobic and isotonic exercises with a goal of achieving a sustained heart rate of approximately 70% to 85% of the maximum predicted heart rate at least 3 or 4 times per week has been shown to improve survival. For beginners, a supervised exercise or rehabilitative program, in which 50% to 70% of maximal predicted heart rate is achieved, is also helpful. Isometric exercises are not recommended because they increase myocardial oxygen demand substantially.
2. **Diet.** A low-fat diet that includes cereals and grains, skimmed dairy products, fruits and vegetables, fish, and lean meats should be recommended and this is effective in providing cardiovascular risk reduction in patients with CAD. These are also integral components of the "Mediterranean Diet," which has been shown to reduce cardiovascular risk. A multidisciplinary approach to the care of patients with CAD that includes a nutritionist/dietician can be quite helpful in personalizing patients' eating habits.
3. **Smoking cessation.** Cigarette smoking is associated with progression of atherosclerosis, increased myocardial demand due to an α-adrenergic increase in coronary tone, and adverse effects on hemostatic values, all of which can lead to worsening of stable angina. Smoking cessation decreases cardiovascular risk among patients with established CAD, including patients who have undergone CABG. Physician counseling is the best approach to achieve this goal and adjunctive therapies include nicotine replacement patches, gum, or sprays, or medications such as bupropion and varenicline.
4. **Psychological factors.** Anger, hostility, depression, and stress are shown to adversely affect CAD. Results of small, nonrandomized trials show that biofeedback and various relaxation techniques can help modify these factors.

V. RECOMMENDED APPROACH TO STABLE ANGINA

A. The following approach is suggested for the treatment of patients with stable angina.

1. It is reasonable to risk stratify patients with stable angina using stress testing with imaging, such as nuclear isotope imaging or echocardiography.
   a. LV systolic function should be assessed with echocardiography to guide therapy and to identify patients with moderate LV systolic dysfunction.
   b. Patients with small perfusion defects or small wall–motion abnormalities, high threshold for ischemia, normal LV systolic function, and clear symptoms should be treated with medication.

2. If symptoms continue after medical therapy is maximized, angiography should be planned. Coronary angiography should also be performed for patients with evidence of impaired perfusion involving multiple territories, a low threshold for ischemia, and moderate LV systolic dysfunction.
3. **Single-vessel disease.** If a patient has single-vessel CAD that does not involve the LMT or supply a large myocardial territory, medical management with risk factor modification is the appropriate first step.
   a. If patients cannot tolerate medical treatment or have symptoms despite maximum medical therapy, revascularization therapy should be offered.
4. Among patients with **multivessel CAD**, medical treatment remains an alternative for patients who have normal LV systolic function, mild symptoms, and relatively smaller areas of myocardium at risk.
   a. The decision for multivessel PCI versus CABG in this group of patients should be made on an individual basis, taking into consideration the angiographic anatomy, LV function, patient comorbidities, surgical risk, and patient preference.
   b. Any doubt regarding viability of the myocardium at risk should be addressed with appropriate diagnostic studies before revascularization.
5. In patients with "unprotected" LMT stenosis, the previous recommendations of CABG in all patients who are able to undergo surgery have recently been revised. PCI for severe LMT disease may be appropriate in select patients.
6. Regardless of treatment strategy, aggressive risk factor modification, including use of lipid-lowering agents, lifestyle modification, and aspirin therapy, is an essential component of management.

CHAPTER 7

Gus Theodos

Other Ischemic Syndromes: Silent Ischemia and Syndrome X

SILENT ISCHEMIA

I. INTRODUCTION. Silent ischemia represents an underappreciated manifestation of coronary artery disease (CAD), occurring in up to 20% to 40% of patients with stable and unstable coronary syndromes. It is estimated that 195,000 silent first myocardial infarctions (MIs) occur each year, which assumes that 21% of MIs are silent. By definition, patients are asymptomatic, lacking typical or atypical anginal symptoms. Silent ischemia may be documented by a variety of diagnostic modalities, including resting electrocardiogram (ECG), ambulatory ECG (AECG), nuclear scintigraphy, and echocardiography.

II. CLINICAL PRESENTATION. Patients may be loosely categorized into three groups, collectively representing a continuum of silent ischemia.

A. Type I have **asymptomatic** ischemia with no known CAD history with **asymptomatic** MI patterns. Clinicians may discover evidence of subclinical MI from a resting ECG or a preoperative stress test. In the Framingham study, 12.5% of patients with MI had an unrecognized "silent" infarction. Patients may also present with arrhythmias or sudden death from subsequent scar. These patients are considered to have an ineffective "anginal warning system."

In addition, a subset of this group includes patients with **asymptomatic** ischemia without a history of infarction. Silent ischemia is often discovered by stress tests after referral for aggressive primary screening. This type of screening may occur in patients with diabetes, strong family histories, or a high-risk electron beam computed tomography (EBCT) result. Given the increasingly technological nature of medical culture, the prevalence of these patients is likely to rise. AECG is rarely used as a primary screening modality. The American College of Cardiology and American Heart Association (ACC/AHA) guidelines consider the use of AECG for ischemia monitoring in asymptomatic individuals as a class III recommendation.

B. Type II have **symptomatic** MIs but subsequent **asymptomatic** ischemic syndromes. Ischemia is often missed because of a lack of symptoms. Patients in this category are most often encountered after a positive stress test or the rarely ordered AECG. Type II patients may have an abnormal **pain threshold.**

C. Type III encompass the largest patient population with silent ischemia. These patients with known CAD have both **symptomatic** and **asymptomatic** ischemia. Between 20% and 40% of patients with chronic anginal symptoms have silent ischemia. About 75% of ischemic episodes are silent and only 25% are symptomatic.

III. DIAGNOSTIC TESTING. Most patients with silent ischemia are either never identified or identified retrospectively. In the Asymptomatic Cardiac Ischemic Pilot (ACIP) study, patients with frequent silent ischemic events were found to be at increased risk for advanced

coronary disease, including high-risk coronary anatomy such as three-vessel disease. Currently, testing to detect ischemia in asymptomatic patients is controversial. The ACC/AHA guidelines consider the use of exercise ECG testing (without imaging) in asymptomatic patients with possible myocardial ischemia on AECG or severe coronary calcification on EBCT as a *class IIb recommendation*. The use of exercise plus imaging stress testing (echo and nuclear) in asymptomatic patients with a low-risk Duke treadmill score on exercise ECG testing is a *class III recommendation*. In patients with an intermediate- or high-risk Duke treadmill score, it is a *class IIb recommendation.* In *asymptomatic* patients with prior revascularization with high-risk features, periodic stress testing is a *class IIb recommendation*.

IV. MECHANISMS

A. The exact explanation for a lack of symptoms in the face of unequivocal ischemia remains **unknown**. It likely represents abnormal modulation of cardiac **pain perception at different levels in the afferent pathway of the heart**.

B. The association between diabetes and silent ischemia and painless infarction has been attributed to **autonomic neuropathy**. A higher threshold for pain has been related to increased baseline plasma β-endorphin levels and increased age. A potential connection exists between baroreceptor function and pain perception. This may explain the relationships among increased systolic blood pressure, reduced sensitivity to ischemic pain, and the demonstration of anginal relief with carotid sinus stimulation. Results of one study suggested that the gating of afferent signals at the thalamic level is a potential mechanism for silent ischemia. Patients with symptoms had activation of basal frontal, anterior, and ventral cingulate cortices and the left temporal pole. **Cortical activation was limited to the right frontal region in patients with silent ischemia**. It also has been proposed that, among type III patients, asymptomatic ischemia may represent shorter and less severe episodes compared with symptomatic episodes.

V. MANAGEMENT

A. Medications effective in preventing symptomatic ischemia (i.e., nitrates, calcium antagonists, and β-blockers) and in decreasing myocardial O_2 demand are also effective in reducing or eliminating episodes of silent ischemia. In one randomized study, metoprolol was found to be better than diltiazem in reducing the mean number and duration of ischemic episodes. However, the combination of calcium antagonists and β-blockers was more effective than either agent alone. Lipid-lowering therapy has also shown a reduction of ischemia on AECG. The ACC/AHA guidelines currently regard the use of ASA (aspirin), β-blockers, angiotensin-converting enzyme inhibitors, and statins as class I recommendations in asymptomatic patients with evidence of previous MI and class IIa recommendations in patients without history of previous MI. It has also been postulated that ranolazine may also reduce ischemia before symptoms become present.

B. The goal of therapy remains controversial. It is not clear whether therapy should be guided by ischemia or angina. The ACIP study revealed no difference in benefit from either of these approaches. However, 2-year follow-up data from this study demonstrated improved prognosis with initial revascularization compared with angina- or ischemia-guided medical therapy. The Swiss Interventional Study on Silent Ischemia type I (SWISSI I) randomized 54 type I subset patients to treatment with antianginal medications and aspirin versus risk factor modification only. Their findings showed that treatment with the combination of antianginal drug therapy and aspirin appeared to significantly reduce cardiac events, including cardiac death, nonfatal MI, or acute coronary syndrome. In addition, these patients had consistently lower rates of exercise-induced ischemia during follow-up. The SWISSI II study randomized 201 patients with type II silent ischemia to percutaneous coronary intervention (PCI) versus ongoing anti-ischemic medical therapy. The results showed a significant decrease in rates of cardiac death, nonfatal MI, and subsequent

need for revascularization in patients in the PCI group over a 10-year follow-up period. Similarly, in patients with type I silent ischemia, with an ineffective "anginal warning system," it has been suggested that it may be reasonable to treat silent ischemia in a manner equivalent to that for symptomatic ischemia in the general population in terms of revascularization and medical therapy.

VI. PROGNOSIS. Myocardial ischemia, whether symptomatic or asymptomatic, is associated with poorer outcomes among patients with CAD. Patients with frequent and accelerating episodes of ST-segment depression on AECG monitoring are at higher risk for subsequent cardiac events than patients with few or no such episodes. The Copenhagen Holter study examined the significance of ischemic changes on AECG in asymptomatic, healthy individuals between the ages of 55 and 75 years (type I subset). They found that patients with silent ischemia had a threefold higher risk of subsequent cardiac events over a 5-year follow-up period. Circadian effects of asymptomatic ST depression on AECG have been noted with changes being more common in the morning hours; however, nocturnal ST-segment changes have been associated with multivessel CAD or left main narrowing. It has not been proven conclusively, however, that detection of silent ischemia is an independent risk factor for future cardiac events.

VII. CONTROVERSIES

A. Patients with silent ischemia on AECG monitoring represent heterogeneous populations. This may be a marker of unstable, complex coronary plaque or microvascular dysfunction. Results of the angiographic substudy of the ACIP study suggested that most patients with silent ischemia have proximal coronary lesions or complex coronary plaques. This hypothesis has not been tested in a larger population and continues to be investigated.

B. The potential role of **AECG monitoring** for ischemia still needs to be determined to assess its utility compared with more commonly used tests, such as exercise testing with thallium imaging. Different populations should be carefully examined at specific times after their events to answer these questions. Currently, the exercise ECG test remains the most useful and validated screening test for significant CAD.

C. **Medical therapy** should be used to decrease or eliminate ischemia; however, the relative role of medical therapy compared with revascularization in asymptomatic patients with demonstrable ischemia remains unclear.

D. **Coronary artery calcium** scanning to screen asymptomatic patients for CAD is now a *class IIa indication* in those patients with an intermediate (10% to 20%) 10-year risk of cardiac events based on the Framingham risk score or other global risk algorithm and for asymptomatic patients aged 40 years and older with diabetes mellitus.

SYNDROME X

I. INTRODUCTION. Syndrome X is defined as the constellation of effort-induced **anginalike discomfort** in the setting of **angiographically normal coronary arteries** (without inducible spasm on ergonovine provocation testing). This chest pain is usually indistinguishable from traditional ischemic angina caused by obstructive coronary disease and is, therefore, considered a diagnosis of exclusion.

II. PRESENTATION. In the clinical setting, syndrome X is a diagnosis given to patients with persistent **anginal symptoms**, often with abnormal stress testing despite a **normal angiogram** and **negative workup** for noncardiac chest pain. Up to 25% of all coronary angiograms performed in the United States for symptoms of chest pain are normal; yet, most cardiologists do not routinely use ergonovine provocation or intravascular ultrasound to evaluate for variant angina or angiographically silent coronary atherosclerosis in this subset of patients. When intravascular ultrasonography studies have been performed

in these patients, a spectrum of findings ranging from normal vessels to intimal thickening to nonobstructive atheromatous plaque has been reported. Syndrome X has an increased occurrence in women (3:1 preponderance), both premenopausal and postmenopausal. Of note, abnormal cardiac physical examination findings and left ventricular (LV) dysfunction on stress testing are both uncommon in syndrome X.

III. ETIOLOGY AND PATHOPHYSIOLOGY. Syndrome X represents a heterogeneous population and may represent multiple processes with varying causes. **Endothelial dysfunction, microvascular ischemia, and abnormal pain perception have all been implicated in the genesis of this disorder**. Endothelial dysfunction as demonstrated by abnormal coronary flow reserve (CFR), single positron emission computed tomography stress, and positron emission tomography stress testing is common in these patients. In addition, behavioral and psychiatric conditions often coexist. Specific treatment aimed at managing behavioral issues may lead to symptomatic improvement in chest pain in some patients.

IV. DIAGNOSTIC TESTING. Because syndrome X is a **diagnosis of exclusion**, both traditional obstructive coronary atherosclerosis and causes of noncardiac chest pain must be ruled out before a final diagnosis can be made. Multislice computed tomography angiography may play an increasingly important role in avoiding invasive angiography in some of these patients. Laboratory testing for endothelial dysfunction is not widely utilized in the clinical setting. Abnormal CFR in the catheterization laboratory can help confirm abnormalities in microcirculatory control, often accompanied by endothelial dysfunction in patients with syndrome X. C-reactive protein (high-sensitivity CRP) has been shown to correlate with the severity of symptoms and ECG changes in this population.

V. THERAPY. The **primary goal** of the therapy should be **aggressive cardiac risk factor modification,** including lifestyle changes and lipid treatment, although the **ideal treatment regimen is unknown**. β-Blockers have been shown to be very effective in controlling anginal symptoms in this population and are considered superior to calcium channel blockers and nitrates. Other treatments that have provided benefit include tricyclic antidepressants (imipramine), oral aminophylline, and estrogen in postmenopausal women. Given the recent data on estrogens, caution should be exercised when considering estrogen therapy in patients with suspected syndrome X.

VI. PROGNOSIS. The prognosis for patients with angina and normal coronary arteriograms is generally favorable with good long-term outcomes shown in multiple studies. However, subsets of these patients such as patients with persistent anginal symptoms and/or evidence of significant myocardial ischemia on stress testing seem to be at higher risk and have significantly higher event rates, including premature death, MI, and stroke, than the baseline population. These subsets of patients should be treated aggressively with risk factor modification and counseled regarding lifestyle modification.

VII. OTHER. Although not clearly related to syndrome X, **Takotsubo syndrome** (aka LV apical ballooning syndrome and stress-induced cardiomyopathy) is a condition that has been receiving increasing attention. Clinical features include sudden onset of chest pain, ECG changes (often ST elevation) mimicking an acute MI, usually in the setting of severe emotional distress and catecholamine surge. The angiogram shows normal coronary arteries, and diagnosis is made on the typical appearance seen on LV ventriculogram or echocardiogram with basal hyperkinesis and severe apical systolic wall motion abnormality. Most patients recover LV function and require only hemodynamic and pharmacologic support.

Heart Failure with Systolic Dysfunction

I. INTRODUCTION

A. Heart failure is a complex clinical syndrome characterized by impaired myocardial performance and progressive maladaptive neurohormonal activation of the cardiovascular and renal systems leading to circulatory insufficiency and congestion. Currently, acute heart failure syndromes (AHFS) constitute the most common indication for hospitalization in adults over age 65. With the increasing age of the population, improved survival of patients with acute coronary syndromes, and reduced mortality from other diseases, the incidence and attendant cost of managing patients with heart failure will inevitably increase.

B. Terminology

1. Based on the hemodynamic model, **systolic heart failure** has been defined by the presence of impaired contractility of the left ventricle, most commonly conveyed in an ejection fraction (EF) of < 40% to 50%. This drop in contractility may be associated with chamber dilation and a decreased stroke volume (Fig. 8.1). There is a growing appreciation for the limitations of this classification. The threshold for systolic dysfunction is arbitrary and it is now clear that patients with heart failure with preserved EF suffer similar morbidity and mortality. There is substantial variability in EF determinations made by different imaging modalities. Most importantly, EF correlates poorly with symptoms, cardiac indices, and potential response to pharmacotherapy.
2. In practice, heart failure is a bedside diagnosis that is defined by clinical assessment. Patients may have cardiac dysfunction without symptoms, often referred to as **asymptomatic left ventricular (LV) dysfunction**. Others may have preserved LV systolic function with typical signs and symptoms of heart failure, best referred to as **heart failure with preserved EF** (see Chapter 9).
3. The major pathophysiologic process in the progression of heart failure is **cardiac remodeling**, in the form of progressive chamber enlargement with an obligatory reduction in EF. Histopathologically, this is associated with myocyte hypertrophy, apoptosis, and necrosis. Molecular alterations including reexpression of a fetal gene program and alterations in excitation–contraction coupling and regulatory proteins occur.
4. In some cases, **myocardial recovery** or **reverse remodeling** is possible with pharmacologic and device therapy.
5. The term **congestive heart failure** is overused and nonspecific, often being applied to states of hypervolemia unrelated to cardiac dysfunction. Conversely, not all patients with heart failure have signs and symptoms of congestion.
6. The term **right heart failure** is used to describe patients with predominantly peripheral signs and symptoms of heart failure with a relative paucity of pulmonary congestion.
7. **Acute decompensated heart failure** or **AHFS** refer to episodes of acute or subacute deterioration of heart failure due to a wide range of precipitants. The vast majority of these events are marked by systemic and pulmonary congestion.

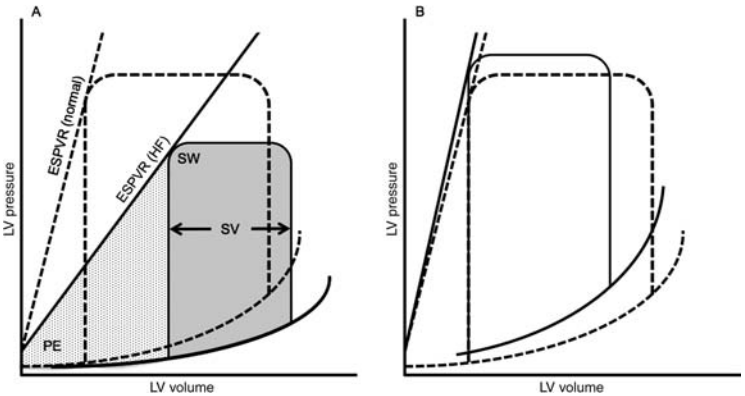

FIGURE 8.1 Pressure–volume loops in normal (dashed line) and heart failure (HF; solid line) patients. **A:** Pressure–volume loops in HF with impaired ejection fraction typically demonstrate a reduction in the end-systolic pressure–volume relationship (ESPVR; i.e., the end-systolic elastance), a representation of contractility. This is typically accompanied by an increase in end-diastolic volume and a reduction in stroke volume (SV) and stroke work (SW; shaded area). At a given ESPVR, a reduction in end-systolic pressure results in an increased SV and reduction in the left ventricular (LV) elastic potential energy (PE; speckled area). **B:** In contrast, patients with HF with preserved ejection fraction have a normal or elevated ESPVR with a left and upward shift in the end-diastolic pressure–volume relationship reflecting decreased myocardial compliance.

II. PATHOGENESIS

A. Heart failure is a progressive disorder initiated by some form of myocardial injury. This injury may range from acute disruptions in myocardial function (myocardial infarction or myocarditis) to one of a number of chronic derangements including familial and metabolic cardiomyopathies or chronic volume or pressure loading related to valvulopathies, intracardiac shunts, or systemic hypertension. Regardless of the initial insult, the compensatory mechanisms that may be beneficial acutely ultimately become maladaptive in the chronic phase.

B. Neurohormonal activation

1. **Activation of the sympathetic nervous system.** Chronic activation of the sympathetic nervous system ultimately results in decreased β-adrenergic receptor responsiveness and decreased norepinephrine stores and sympathetic innervation of the myocardium. Chronically, these changes contribute to myocyte hypertrophy, fibrosis, and necrosis. Extracardiac effects include increased tubular reabsorption of sodium, activation of the renin–angiotensin system (RAS), neurogenic vasoconstriction, and vascular hypertrophy.
2. **Activation of the RAS.** As heart failure progresses, renal hypoperfusion and sympathetic stimulation of the kidneys result in increased production of renin by the juxtaglomerular apparatus. Renin cleaves circulating angiotensinogen into the biologically inactive angiotensin I, which is subsequently cleaved by angiotensin-converting enzyme (ACE) to the biologically active angiotensin II. Importantly, angiotensin II can be generated in renin and ACE-independent pathways as well. In addition to direct cardiovascular effects, angiotensin II stimulates aldosterone production by the zona glomerulosa of the adrenal cortex, which in turn promotes reabsorption of sodium in exchange for

potassium in the distal nephron. Chronically, aldosterone results in the promotion of hypertrophy and fibrosis in the vasculature and myocardium, endothelial dysfunction, and inhibition of norepinephrine uptake.

3. **Other neurohormonal derangements.** Inappropriate production of arginine vasopressin has an antidiuretic effect contributing and worsens vasoconstriction. Endothelin, neuropeptide Y, and other peripheral vasoconstrictors further enhance vascular tone.

III. CLASSIFICATION

A. The American College of Cardiology and the American Heart Association (ACC/AHA) guidelines currently classify heart failure on the basis of the evolution of the disease across a continuum:

1. **Stage A:** patients at high risk for developing heart failure without structural heart disease or symptomatic heart failure.
2. **Stage B:** patients with structural heart disease who have not yet developed symptoms of heart failure.
3. **Stage C:** patients with structural heart disease with prior or current symptoms of heart failure.
4. **Stage D:** patients with refractory end-stage heart failure who require specialized advanced treatment.

B. The **New York Heart Association (NYHA) functional classification**, although subjective and vague, remains the most commonly used standard by which the severity of functional impairment is graded (Table 8.1).

C. The **Killip classification** grades the severity of signs of decompensated heart failure in the post-acute coronary syndrome setting and is highly predictive of 30-day mortality.

VI. ETIOLOGY.

It is essential to make every effort to identify the specific etiology of heart failure as it may have implications for management and prognosis. While ischemic cardiomyopathy is by far the most common cause of systolic heart failure, a diverse array of disease states can culminate in this phenotype (Table 8.2).

TABLE 8.1 New York Heart Association Functional Classification

Class	Description
I	Patients have cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or anginal pain.
II	Patients have cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitations, dyspnea, or anginal pain.
III	Patients have cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.
IV	Patients have cardiac disease resulting in an inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

TABLE 8.2 Etiologies of Heart Failure

- Dilated cardiomyopathy
  - Idiopathic
  - Familial
- Hypertrophic cardiomyopathy
- Restrictive cardiomyopathy
- Unclassified cardiomyopathies
  - Fibroelastosis
  - Mitochondrial cardiomyopathy
  - Left ventricular noncompaction
- Specific cardiomyopathies
  - Ischemic cardiomyopathy
  - Stress-induced cardiomyopathy
  - Valvular obstruction or insufficiency
  - Hypertensive
  - Inflammatory (lymphocytic, eosinophilic, giant cell myocarditis)
  - Infectious (Chagas disease, Lyme disease, HIV, enterovirus, adenovirus, CMV, bacterial or fungal infections)
- Metabolic
  - Endocrine (thyroid diseases, adrenal insufficiency, pheochromocytoma, acromegaly, diabetes mellitus)
  - Familial storage disease (hemochromatosis, glycogen storage disease, Hurler's syndrome, Anderson-Fabry disease)
  - Electrolyte deficiency syndromes (hypokalemia, hypomagnesemia)
  - Nutritional deficiencies (kwashiorkor, anemia, beriberi, carnitine and selenium deficiency)
  - Amyloid
  - Familial Mediterranean fever
- Systemic diseases
  - Connective tissue disorders (SLE, polyarteritis nodosa, rheumatoid arthritis, scleroderma, dermatomyositis, polymyositis, sarcoidosis)
  - Muscular dystrophies (Duchenne's, Becker's, myotonic, limb girdle)
  - Neuromuscular (Friedreich's ataxia, Noonan's disease)
  - Toxins (alcohol, catecholamines, cocaine, anthracyclines and other chemotherapeutics, radiation)

CMV, cytomegalovirus; HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.
Modified from WHO Classification.

A. Ischemic cardiomyopathy is the cause of 60% to 75% of cases of systolic heart failure in industrialized countries. It is defined as **cardiomyopathy in the presence of prior extensive myocardial infarction, hibernating myocardium, or severe coronary artery disease**. However, the mere ***presence of obstructive coronary artery disease does not equal ischemic cardiomyopathy as it is possible to have coronary artery disease superimposed with a nonischemic etiology of heart failure***. A careful assessment of the coronary anatomy, the burden of ischemia, and the presence of infarcted and viable myocardium must be made and an assessment of the proportionality of these findings to the degree of myocardial dysfunction should be made. The risks and benefits of percutaneous or surgical revascularization should be assessed in all patients with ischemic cardiomyopathy. Extensive observational data have suggested a benefit for coronary artery bypass grafting (CABG) compared with medical therapy alone in moderate to severe LV systolic dysfunction. Registry data suggest that CABG is superior to percutaneous coronary intervention in patients with reduced EF. However, recently released 5-year data from the Surgical Treatment for Ischemic Heart Failure (STICH) trial demonstrated no difference in 5-year mortality for patients with left ventricular ejection fraction (LVEF) < 35% undergoing CABG in addition to optimal medical therapy versus optimal medical therapy alone. Furthermore, a substudy of STICH demonstrated that preoperative viability testing did not effectively predict whether patients derived benefit from CABG. Notably, patients with left main trunk disease and severe angina were excluded from the study and these patients should continue to be treated aggressively with revascularization.

B. Dilated cardiomyopathy. In 20% to 30% of cases of heart failure with systolic dysfunction, the precise etiology is not established and a diagnosis of nonischemic, dilated, or idiopathic cardiomyopathy is made. Patients with **dilated cardiomyopathy typically have a better prognosis than their ischemic counterparts**.

1. Dilated cardiomyopathy is frequently attributed to the residual effects of **subclinical viral myocarditis**. Reverse transcription polymerase chain reaction analysis of endomyocardial biopsies from patients with dilated cardiomyopathy demonstrates amplification of viral genomes in approximately two-thirds of cases. Any virus can cause myocarditis, but, owing to its ubiquity, coxsackie B virus is the most epidemiologically important.
2. **Familial dilated cardiomyopathy.** It is now recognized that 25% to 50% of cases of dilated cardiomyopathy may have a genetic basis. Conditions are typically autosomal dominant and show variable penetrance. A detailed three-generation family history is essential at the time of initial evaluation. If the family history suggests a genetic predisposition, clinical screening of family members is appropriate and genetic testing can be performed following referral to a genetic counselor. Importantly, only 15% to 25% of presumed familial dilated cardiomyopathies have identifiable genetic alterations.

C. Hypertensive and diabetic cardiomyopathy are seldom considered as stand-alone diagnoses. Progression from LV hypertrophy to overt dysfunction in hypertensive patients (the so-called burnt-out hypertensive heart) most likely results from progressive microvascular ischemia. Hypertension and diabetes also contribute significantly to the development of coronary artery disease and ischemic cardiomyopathy.

D. Cardiotoxic agents. The list of toxins that can produce cardiomyopathy is extensive. Identification of the toxin and removal of the offending agent may halt the progression of or even reverse LV dysfunction.

1. **Chemotherapeutic agents. Anthracycline** toxicity can cause myocyte destruction and cardiomyopathy. Patients who receive a cumulative doxorubicin equivalent dose of < 400 mg/m^2 are at low risk for this syndrome, while those receiving a cumulative dose > 700 mg/m^2 have an approximately 20% lifetime risk of developing cardiomyopathy. Other cardiotoxic drugs that require careful cardiac monitoring include **cyclophosphamide** and **trastuzumab**. Trastuzumab

(Herceptin) is now frequently used in the treatment of human epidermal growth factor receptor 2 positive breast cancer and has been associated with a reversible cardiomyopathy in 2% to 7% of patients undergoing treatment. Antiangiogenic drugs such as sunitinib can also cause cardiotoxicity and uncontrolled hypertension.

2. **Alcohol** consumption is thought to represent a common cause of toxin-mediated cardiomyopathy; however, there is limited observational data on the actual incidence of the cardiomyopathy or the volume of alcohol consumption necessary to induce it. Total abstinence from alcohol may result in complete resolution, whereas continued use is associated with a 3- to 6-year mortality exceeding 50%.
3. **Stimulant drugs** including cocaine and methamphetamine may result in the development of heart failure via multiple derangements including progressive concentric hypertrophy and recurrent myocardial infarction.
4. **Toxin exposures** including lead, arsenic, and cobalt can result in progressive myocardial dysfunction.

E. Inflammatory cardiomyopathy (i.e., myocarditis) is discussed in detail in Chapter 11.

F. Tachyarrhythmia-induced cardiomyopathy can complicate the course of atrial fibrillation, atrial flutter, ectopic atrial tachycardia, and even occult sustained ventricular tachycardia and frequent premature ventricular contractions (> 20% to 30% of beats). In general, it is thought that persistent tachycardia in excess of 110 bpm is required to induce LV dysfunction. This is a critical diagnosis to make, as treatment of the underlying tachyarrhythmia generally results in complete resolution of the cardiomyopathy.

G. Peripartum cardiomyopathy is defined as a dilated cardiomyopathy occurring between the last month of pregnancy and up to 5 months postpartum. The majority of peripartum cardiomyopathy patients improve with standard heart failure pharmacotherapy, with over 50% of patients experiencing complete normalization of cardiac function.

H. Valvular disorders are common causes of heart failure. Aortic regurgitation and mitral regurgitation (MR) result in chronic volume overload and ultimately culminate in dilated cardiomyopathy. Severe aortic stenosis and outflow tract obstruction commonly lead to progressive LV dysfunction (see Chapters 14 and 15). Surgical correction is the preferred management of severe valvular lesions.

I. Miscellaneous disorders

1. **Thyroid disorders**
   a. **Hypothyroidism** is common in patients with heart failure. Severe hypothyroidism (i.e., myxedema) may cause decreased cardiac output and heart failure. Bradycardia and pericardial effusion can develop in extreme cases of hypothyroidism.
   b. Heart failure may complicate **hyperthyroidism**, especially in elderly patients with low ventricular reserve. Atrial fibrillation is a common accompanying arrhythmia, occurring in 9% to 22% of patients with thyrotoxicosis. Nonspecific symptoms such as fatigue, weight loss, and insomnia predominate. Previously stable angina may become unstable. Patients treated with amiodarone may develop a wide range of thyroid disorders ranging from abnormal thyroid function tests to overt amiodarone-induced thyrotoxicosis or hypothyroidism. Both conditions can occur in otherwise normal thyroid glands.
2. **Thiamine deficiency (beriberi).** Although rare in industrialized countries, thiamine deficiency is still prevalent in the developing world. It can also occur in alcoholics or individuals observing fad diets. Wet beriberi includes features of **high-output cardiac failure such as marked edema, peripheral vasodilatation, and pulmonary congestion**. The signs and symptoms of dry beriberi include glossitis, hyperkeratosis, and peripheral neuropathy. The laboratory diagnosis is made using decreased RBC transketolase and 24-hour urine thiamine

levels. Severe cases can present with lactic acidosis. Intravenous therapy with 100 mg of thiamine followed by daily oral supplementation can result in dramatic clinical improvement. Chronic use of high-dose diuretics may be complicated by subclinical thiamine deficiency of unknown significance.

3. **Other nutritional deficiencies.** Carnitine and selenium deficiency may result in dilated cardiomyopathy complicating chronic parenteral nutrition.
4. **High-output heart failure from anemia.** Acute anemia caused by rapid blood loss is associated with decreased cardiac output due by hypovolemic shock. In contrast, chronic anemia can be associated with symptoms of heart failure due to compensatory mechanisms. These include fluid retention, increased cardiac output, decreased vascular resistance, and increased 2,3-diphosphoglycerate with a resultant rightward shift in the oxyhemoglobin dissociation curve. Moderate degrees of chronic anemia (hemoglobin < 9 g/dL) typically only result in heart failure symptoms in patients with preexisting cardiac disease. Chronic anemia of severe proportions (hemoglobin < 7 g/dL) may result in high-output heart failure even in individuals with normal hearts. Evaluation and management of the underlying cause and supportive care are advised. Thresholds for transfusion depend on the clinical context and rapidity of blood loss. Iron repletion should be considered in iron-deficient patients and in inpatients is most readily achieved with the daily administration of intravenous ferric gluconate 125 mg for 8 to 10 days.
5. While early in its course **hemochromatosis** may present with restrictive cardiomyopathy, it typically progresses to a mixed or dilated form. Treatment with chelating agents or phlebotomy may improve cardiac function in both primary and secondary forms.
6. **Inherited myopathies** such as Becker's and Duchenne's muscular dystrophies, limb girdle dystrophy, and myotonic dystrophy are associated with dilated cardiomyopathy. Friedreich's ataxia is most commonly associated with hypertrophic cardiomyopathy, but in rare instances can present with a dilated phenotype. Mitochondrial cardiomyopathies may also present with dilated cardiomyopathy.
7. **Cardiac sarcoidosis** can present with LV dysfunction with regional hypokinesis or aneurysmal dilatation. It is frequently associated with conduction abnormalities and ventricular tachyarrhythmias. The diagnosis can be supported with stereotypical findings on cardiac MRI and positron emission tomography (PET). The diagnosis is rare in the absence of extracardiac manifestations.
8. **Chagas disease** caused by the flagellate protozoan *Trypanosoma cruzi* remains a common cause of heart failure in patients from Latin America. In the chronic symptomatic phase, patients typically present with a syndrome of ventricular dysfunction with regional wall motion abnormalities in the absence of obstructive coronary artery disease. This pattern should prompt *T. cruzi* titers in patients from endemic regions.

V. SIGNS AND SYMPTOMS

A. There is a wide spectrum of signs and symptoms in heart failure patients. Subjective changes in signs and symptoms are often difficult to elicit and frequently leave insufficient time lag for therapeutic interventions prior to hospitalization.

1. The most common and earliest presenting symptom is **dyspnea**, typically with exertion. **Orthopnea** is typical with more advanced disease. It is amongst the most sensitive (90%) and specific (90%) signs of decompensated heart failure. As further decompensation occurs, **paroxysmal nocturnal dyspnea** and **Cheyne-Stokes respiratory patterns** may occur.
2. **Fatigue** and **exercise intolerance** are common complaints in patients with heart failure and may reflect diminished cardiac output. Seldom considered but highly prevalent symptoms include **nocturnal cough, insomnia, and depressed mood**.

3. **Palpitations** and **syncope** may occur in patients with underlying arrhythmia and require prompt evaluation.
4. **Anorexia** and **abdominal pain** are common in advanced right heart failure.

B. Physical examination of patients with significant but well-compensated systolic heart failure may reveal no abnormalities. Physical signs vary according to the degree of compensation, the chronicity, and the chamber involvement.

1. **Volume overload** is the hallmark of heart failure. Typical signs of volume overload include the following:
   a. **Weight gain** is a sensitive indicator of congestion.
   b. **Pulmonary rales** due to accumulation of fluid in the pulmonary interstitium and alveoli secondary to high left atrial pressure are commonly referred to as **acute cardiogenic pulmonary edema**. Importantly, rales may be absent in patients with chronic systolic heart failure who develop compensatory perivascular and lymphatic changes.
   c. **Jugular venous distention or elevated jugular venous pressure (JVP)** while not directly reflecting left-sided filling pressures can track these with a reasonable sensitivity (70%) and specificity (79%). JVP should be assessed at a 45° incline with the neck fully exposed. In cases of extreme JVP elevation, the patient may need to be seated upright in order to properly visualize. Five centimeters of water should be added to the vertical distance from the sternal angle to the meniscus of the JVP to account for the distance to the midpoint of the right atrium. Compression of the right upper quadrant and a resultant positive **hepatojugular reflex** (defined as a sustained increase in JVP of ≥4 cm) increase the sensitivity of the JVP for detecting congestion.
   d. **Pedal edema** by some estimates is only present in 30% of patients with decompensated heart failure and is somewhat nonspecific, as it may reflect venous insufficiency, nephrotic syndrome, cirrhosis, or concomitant treatment with calcium channel blockers or thiazolidinediones.
   e. **Ascites and hepatomegaly** may occur. When accompanied by a palpably pulsatile liver, hepatomegaly suggests severe tricuspid regurgitation.
   f. A holosystolic murmur of **MR** is often present in the setting of LV dilatation.
   g. **A third heart sound** (S_3 gallop) is best heard with the bell of the stethoscope in the left lateral position and signifies increased LV end-diastolic pressure.
2. Often neglected are the subtle signs of **peripheral hypoperfusion**.
   a. **Pulsus alternans** or a low-amplitude pulse in the absence of alternative explanations reflects severely impaired cardiac output.
   b. Tachycardia and narrow pulse pressure also suggest diminished cardiac output.
   c. Lethargy, pallor, mottled skin, cool extremities, and poor capillary refill are typical signs.
   d. **Hypotension** itself may be one of the most important clinical findings in heart failure. Several studies have demonstrated that a systolic blood pressure < 90 mm Hg is a strong predictor of morbidity and mortality.

VI. DIAGNOSTIC EVALUATION

A. Laboratory work is used to diagnose potentially reversible causes, identify comorbidities, monitor and correct abnormalities before or during treatment, and assess the disease severity.

1. A **comprehensive metabolic panel** should be assessed on initial evaluation and then subsequently based on clinical judgment. Particular attention should be paid to the presence of hyponatremia, which portends a worse prognosis. Hypokalemia is common in the setting of ongoing diuretic therapy. Hyperkalemia can be seen in the context of overaggressive potassium repletion and ongoing treatment with ACE or aldosterone inhibitors or in diabetic patients with

associated type IV renal tubular acidosis. Aside from the pragmatic considerations, many real-world registries have identified elevated blood urea nitrogen (BUN) and creatinine as powerful predictors of outcome. Renal function must also be taken into account when considering therapy with renally excreted drugs. Transaminitis and in some cases a cholestatic pattern of liver function test abnormalities may be seen in the context of right heart failure.

2. **Anemia** is present in up to 40% of heart failure patients and is associated with increased mortality and functional impairment. While frequently due to anemia of chronic disease, a thorough diagnostic evaluation should be performed.
3. The natriuretic peptides **B-type natriuretic peptide (BNP) and N-terminal pro–B-type natriuretic peptide (NT-proBNP)** are released in the setting of increased ventricular dilation or wall stress. Normal ranges (BNP < 100 pg/mL; NT-proBNP < 125 pg/mL if age < 75 years and < 450 pg/mL if age ≥75 years) must be interpreted in the context of associated conditions known to alter levels. Increasing age and worsening renal function are associated with increased levels. There is an inverse relationship between natriuretic peptides and body mass index.
   a. **Screening for heart failure.** Although cardiac dysfunction has been associated with elevated natriuretic peptide levels, the sensitivity is relatively low in asymptomatic patients and is highly dependent on the cut-off levels chosen. In general, routine assessment of BNP is not recommended as a screening test for structural heart disease in asymptomatic patients.
   b. **Diagnosing heart failure.** The primary use of natriuretic peptides remains the diagnosis of heart failure in symptomatic patients particularly when the diagnosis is unclear. The high negative predictive value (up to 90%) in this setting allows BNP testing to be useful to rule out a cardiac cause of symptoms. With the growing epidemic of obesity, it is important to remember that ***normal natriuretic peptide levels may be present in morbidly obese patients with decompensated heart failure.***
   c. **Management of heart failure.** While still controversial, there is emerging evidence that serial measurements of natriuretic peptides may be beneficial in guiding outpatient heart failure management and may result in decreased heart failure–related mortality versus usual care.
   d. **Determining prognosis of heart failure.** Data now suggest that natriuretic peptide levels are closely correlated with morbidity and mortality in patients with both established heart failure and other cardiovascular diagnoses (e.g., stable coronary artery disease, acute coronary syndromes, pulmonary hypertension, and atrial fibrillation).
4. **Other biomarkers.** A growing list of biomarkers assessing systemic inflammation, oxidative stress, extracellular matrix remodeling, and myocyte injury is commercially available or in development. While some of these provide useful prognostic information, it is not clear how to best integrate them into the diagnosis and management of heart failure.
5. **Thyroid function testing** is warranted for all patients with a new diagnosis of heart failure.
6. Iron studies including ferritin, serum iron, and total iron binding capacity (with calculation of percent transferrin saturation) should be performed to screen for hemochromatosis and occult iron deficiency.
7. Standard laboratory screening for **modifiable cardiovascular risk factors** including fasting lipid panel and serum glucose should be obtained.

B. **The electrocardiogram (ECG)** may provide important information pertaining to the cause and management of heart failure and is a recommended component of the evaluation of any patient with a clinical diagnosis of heart failure.
   1. It is important to look for evidence of prior myocardial infarction, chamber enlargement and hypertrophy, conduction disease, and supraventricular or ventricular arrhythmias.

2. Specific diagnoses can be suggested in the ECG. Cardiac amyloidosis classically presents with low voltages and a pseudoinfarction pattern in the anterior leads in stark contrast to echocardiographically thickened walls. Arrhythmogenic right ventricular (RV) cardiomyopathy may present with epsilon waves or localized prolongation (> 110 milliseconds) of the QRS complex in the right precordial leads.
3. The ECG is an important means of assessing **dyssynchrony**. Marked first-degree atrioventricular (AV) block or very short AV delays in the presence of paced rhythms may contribute to AV dyssynchrony. The presence of QRS prolongation > 120 milliseconds (particularly left bundle branch block morphologies with QRS > 130 milliseconds) suggests interventricular dyssynchrony and remains the most important predictor of response to cardiac resynchronization therapy.
4. **Holter or event monitors** are often useful in identifying occult arrhythmia and arrhythmia burden.

C. Examination of the **chest radiograph** should include an assessment of the heart size and the condition of the pulmonary parenchyma. Determinations of cardiac size are best restricted to standard posteroanterior projections, as "portable" anteroposterior projections will magnify the cardiac silhouette. Lateral projections are useful to assess for RV enlargement, with associated filling of the retrosternal space. A normal cardiac silhouette does not exclude systolic or diastolic dysfunction. The lung field abnormalities may range from mild engorgement of the perihilar vessels to bilateral pleural effusions, Kerley B lines, and frank pulmonary edema.

D. Echocardiography is perhaps the most useful diagnostic test in the evaluation of patients with heart failure. It can provide useful information pertaining to the etiology and prognosis of heart failure. As described in later sections, echocardiography also plays a key role in guiding heart failure therapy.

1. **Etiology of heart failure.** Regional wall motion abnormalities occurring in an anatomic coronary artery distribution are suggestive of ischemic cardiomyopathy. However, regional wall motion abnormalities can also be seen in the context of nonischemic dilated cardiomyopathy, stress-induced cardiomyopathy, and infiltrative cardiomyopathies (with inferobasal wall motion abnormalities classically seen in the setting of cardiac sarcoidosis). The presence and severity of valvular stenosis or insufficiency can be assessed as can the relative dysfunction of the right and left ventricles.
2. **Prognosis in heart failure.** The following parameters are useful in assessing the risk of heart failure–associated morbidity and mortality.
   a. **EF and LV dimensions.** While correlating poorly with heart failure symptoms, exercise capacity, and oxygen consumption, the EF provides valuable prognostic information with morbidity and mortality closely linked to EF and LV volumes. The American Society of Echocardiography recommends that assessment of EF and LV volumes be made using the biplane Simpson's method of disks.
   b. **LV mass.** Remodeling in the failing heart results in increased LV mass due to eccentric hypertrophy, which worsens prognosis. Eccentric hypertrophy is defined echocardiographically as an LV mass > 95 g/m^2 in women and > 115 g/m^2 in men with a regional wall thickness (2 × posterior wall thickness/LV end-diastolic dimension) of ≤0.42.
   c. **The myocardial performance index (Tei index).** The Tei index provides a useful assessment of systolic and diastolic function and is equal to (the isovolumic contraction time + the isovolumic relaxation time)/the ejection time. All dimensions are obtained via pulse wave or tissue Doppler. A Tei index of > 0.77 in patients with dilated cardiomyopathy is highly predictive of cardiovascular morbidity and mortality.
   d. **Measures of diastolic dysfunction.** Many of the measures of diastolic dysfunction detailed in Chapter 9 have powerful prognostic ability in patients

with systolic heart failure. The presence of a restrictive filling pattern ($E/A > 2$, deceleration time < 115 to 150 milliseconds) persisting despite Valsalva maneuver is a particularly ominous finding.

E. Other imaging modalities

1. **Cardiac magnetic resonance (CMR) imaging** (Chapter 51). CMR offers unparalleled myocardial tissue characterization and allows for myocardial viability assessment. As such, it is an increasingly useful tool in the diagnosis of specific cardiomyopathies (e.g., LV noncompaction and cardiac sarcoidosis). The distribution of late gadolinium hyperenhancement representing scar can effectively discriminate between ischemic and nonischemic causes of fibrosis. Cine MRI provides accurate assessments of chamber volumes and LV and RV systolic function that can be performed in arbitrary tomographic views. Major limitations are incompatibility with most implanted electronic cardiovascular devices and the potential for nephrogenic sclerosing fibrosis with the use of gadolinium-based contrast agents in patients with preexisting renal insufficiency (see Chapter 51).
2. **Nuclear imaging.** Single photon emission computed tomography (SPECT) and PET imaging are primarily of use in ruling out myocardial ischemia and/or viability. **Viability assessment** (i.e., discriminating between scarred and hibernating myocardium) is critical in the assessment of patients with heart failure and coronary artery disease and the potential for myocardial recovery with revascularization. This can be achieved with PET using concomitant flow and metabolism tracers (typically [^{18}F]fluorodeoxyglucose) or thallium 201 SPECT redistribution imaging (see Chapter 50). There is growing evidence that PET is superior to SPECT in patients with systolic dysfunction, and when available it should be used preferentially in patients with an LVEF < 35%. Dobutamine stress echocardiography and CMR are alternative means of assessing viability. Radionuclide ventriculography using multiple-gated acquisition scanning has long served as the gold standard for precise serial measurements of the LVEF (classically in the evaluation of patients receiving cardiotoxic chemotherapeutics). Increasingly, however, it is being surpassed by CMR and three-dimensional echocardiography.

F. Right heart catheterization (see Chapter 60). Invasive hemodynamic monitoring is often helpful in the diagnosis and inpatient management of heart failure. Right heart catheterization can be combined with exercise testing or infusions of inotropic or vasodilatory agents to study their hemodynamic effects. Reasonable indications for right heart catheterization include short-term management of acute cardiogenic shock, evaluation of patients for cardiac transplantation or mechanical circulatory support, clarification of hemodynamics in the context-specific comorbidities (e.g., suspected RV infarction or mechanical complications of myocardial infarction), adjustment of therapy in patients with recurrent or refractory symptoms, and optimization of medical therapy in order to facilitate weaning from inotropes.

1. **Cardiac output/index** is one of the important measurements provided by right heart catheterization. It can be determined using the thermodilution technique or the Fick method using an estimated or derived oxygen consumption and a directly measured mixed venous oxygen saturation (MVO_2).
2. **Pulmonary capillary wedge pressure (PCWP)** should be measured in all cases. An inability to normalize the PCWP (< 16 mm Hg) with pharmacotherapy was shown in the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial to confer a twofold increased risk of mortality.
3. **Right atrial pressure** is an important indicator of volume status and right heart function. An elevated central venous pressure has been shown to be the most important predictor of worsening renal function during hospitalizations for acute decompensated heart failure.

G. Coronary angiography (see Chapter 64). There are many approaches to determining which patients with systolic heart failure warrant evaluation by coronary angiography. The Heart Failure Society of America recommends performing coronary angiography in patients with a high pretest probability of underlying ischemic cardiomyopathy and who are candidates for percutaneous or surgical revascularization. At a minimum, patients meeting this description should undergo some form of noninvasive stress testing. Some centers advocate for a baseline coronary angiogram in all patients with newly established systolic heart failure regardless of risk factors or presentation.

H. Endomyocardial biopsy (see Chapter 61) is indicated only when a specific primary myocardial disease is suspected and other causes of decompensation have been ruled out. A recent AHA/ACC/ESC writing group identified 14 clinical scenarios in which there is an incremental diagnostic, prognostic (e.g., amyloidosis), or therapeutic (e.g., giant cell myocarditis) value to biopsy that can be weighed against the procedural risk.

I. Cardiopulmonary exercise testing (metabolic stress testing) while not recommended as part of the routine evaluation of patients with heart failure should be considered in the context of symptoms out of proportion with objective measures of disease severity, discriminating between cardiac and pulmonary etiologies of dyspnea, or assessing candidacy for cardiac transplantation or mechanical circulatory support. Several routinely measured parameters are highly predictive of prognosis in patients with established heart failure.

1. **Peak oxygen consumption (Vo_2)** is perhaps the most important parameter in objectively describing functional capacity and prognosticating. Normal values based on age and sex are indexed to body weight, with a normal value being > 84% predicted. Patients being considered for heart transplantation undergo risk stratification with a metabolic stress test. Patients with a peak Vo_2 < 14 mL/kg/min or < 50% predicted are at increased risk for adverse cardiovascular events and if the limitation is deemed to be cardiac should be considered for transplantation. Interpretation of the peak Vo_2 is highly dependent on the adequacy of effort as assessed by the respiratory exchange ratio (RER). The RER is the ratio of Vco_2/Vo_2 and is at steady state an estimate of the respiratory quotient. It signifies the conversion to anaerobic metabolism and the sudden rise in co_2 production occurring with the onset of metabolic acidosis. Failure to achieve an RER > 1.05 suggests insufficient effort or premature termination of the study. Up to 50% of heart failure patients are incapable of achieving an adequate RER, with a modified Bruce treadmill protocol necessitating the use of alternative protocols.
2. **Ventilatory anaerobic threshold** is another means of assessing the adequacy of effort and represents the point at which minute ventilation (V_E) increases out of proportion with Vo_2 (typically occurring at 60% to 70% of peak Vo_2).
3. **V_E/Vco_2 slope** is a dimensionless ratio indicating the relationship between minute ventilation and CO_2 production. The slope is elevated in most patients with heart failure and is inversely related to cardiac output at peak exercise. A slope > 35 identifies higher risk individuals independently of peak Vo_2.

J. Sleep study. Obstructive sleep apnea and central sleep apnea are common comorbidities contributing adversely to the pathogenesis and prognosis of patients with heart failure. There should be a low threshold for appropriate testing.

VII. TREATMENT.

The effective management of heart failure relies on appreciating the distinction between acute and chronic therapies.

A. Acute heart failure syndromes. In the United States, AHFS continue to constitute the most common indication for hospital admission in adults over age 65 years. These hospitalizations represent an inflection point in the course and prognosis of the chronic disease, with 90-day and 1-year postdischarge mortality as high as 14%

TABLE 8.3 Precipitants of Acute Decompensated Heart Failure

Medication nonadherence
Myocardial ischemia, infarction
Arrhythmias (tachyarrhythmias, bradycardia)
Infection
Anemia
Alcohol consumption
Pregnancy
Worsening hypertension
Acute valvular insufficiency
Drugs that can acutely worsen HF symptoms
Calcium channel antagonists
β-Blockers
Nonsteroidal anti-inflammatory drugs
Thiazolidinediones
Antiarrhythmic agents (all class I agents, sotalol)

and 37%, respectively. Only 20% of AHFS represent patients with de novo heart failure. The majority are patients with worsening chronic heart failure. The initial management goals include symptom improvement, decongestion, and hemodynamic stabilization with optimization of tissue perfusion. It is important to attempt to identify and correct any precipitating factors (Table 8.3).

1. **Invasive hemodynamic monitoring**
   a. **Pulmonary artery catheter.** The **ESCAPE** trial demonstrated that the routine use of a pulmonary artery catheter in the management of patients with AHFS did not result in a reduction in subsequent hospitalizations or mortality but did result in an increase in anticipated complications. The use of a pulmonary artery catheter should therefore be restricted to the scenarios detailed above where there is need for clarification of cardiac indices or filling pressures and in critically ill patients failing to respond to standard therapies. When available, a PCWP of > 18 mm Hg suggests cardiogenic pulmonary edema and a cardiac index of < 2.0 L/min/m^2 is consistent with cardiogenic shock.
   b. **Arterial catheter.** Continuous blood pressure monitoring with an arterial catheter can be useful in cases with marginal blood pressure and allows for optimal titration of intravenous vasodilators.
2. **Maximizing oxygenation** is vital. All patients with acute cardiogenic pulmonary edema should be positioned upright and receive supplemental oxygen. **Noninvasive positive pressure ventilation (NIPPV)** should be considered in those with ongoing increased work of breathing, respiratory acidosis, or persistent hypoxemia. The Noninvasive Ventilation in Acute Cardiogenic Pulmonary Edema (**3CPOE**) trial demonstrated that NIPPV results in more rapid resolution of symptoms and metabolic derangements than continuous positive airway pressure (CPAP) ventilation or standard oxygen therapy. While there was no evidence of a reduction in short-term mortality, this can be an invaluable tool

often forestalling intubation. Patients who fail to respond to NIPPV should be promptly intubated. The use of positive end-expiratory pressure (PEEP) can be effective in improving oxygenation, but high levels of PEEP come at the cost of reduced systemic venous return and cardiac output, which may be problematic in patients in shock.

3. **Vasodilators.** In the absence of symptomatic hypotension, intravenous vasodilators are the first-line therapy for the management of cardiogenic pulmonary edema.
   a. **Nitroglycerin** reduces LV filling pressures via venodilation and to a lesser extent via systemic afterload reduction. It may be given rapidly in the emergency setting (0.4 to 0.8 mg, given sublingually every 3 to 5 minutes) and by means of intravenous infusion in the subacute setting (starting dosage of 0.2 to 0.4 μg/kg/min), with titration every 5 minutes on the basis of symptoms or mean arterial pressure (MAP). While there is no maximal dose, increasing beyond 300 to 400 μg/min likely yields no additional benefit and should prompt the addition of another vasodilator. Tachyphylaxis can occur with high-dose infusions. Headache is the most common side effect, and use is contraindicated in the setting of recent use of phosphodiesterase-5 (PDE-5) inhibitors.
   c. **Sodium nitroprusside** is a potent vasodilator with balanced venous and arteriolar effects. It requires careful hemodynamic monitoring (typically by arterial line). A starting dosage of 0.1 to 0.2 μg/kg/min is used and titrated every 5 minutes to achieve a clinical response while maintaining an MAP > 65 mm Hg. Nitroprusside is particularly useful in instances where a rapid and large reduction in afterload is desired (e.g., cardiogenic shock and acute severe aortic regurgitation or MR). While cyanide and thiocyanate toxicity is exceedingly rare with short durations of therapy, nitroprusside should be used with caution in patients with severe renal dysfunction. Long-term, high-dose infusions should be avoided. In patients with myocardial ischemia, nitroglycerin or a combination of nitroglycerine and nitroprusside is preferred to avoid the theoretical risk of coronary steal.
   d. **Nesiritide** is an intravenous vasodilator that gained popularity in the acute care setting because of its ease of use in the absence of invasive hemodynamic monitoring. Typical dosing starts with 2 mg/kg delivered by intravenous bolus followed by an infusion at a rate of 0.01 mg/kg/min for up to 48 hours. The recently published Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (**ASCEND-HF**) trial demonstrated that nesiritide had no effect on death or rehospitalization for heart failure at 30 days when compared with conventional therapy. While providing some reassurance regarding previous safety concerns, these results have led most experts to discourage its use on the basis of lack of efficacy.
4. **Diuretics.** In addition to their ability to gradually reduce intravascular volume, diuretics have an immediate vasodilatory effect, which may be responsible for their prompt symptom relief. Reductions in filling pressures may be associated with augmented forward flow due to optimization of LV and RV mechanics and interventricular interaction. Because many patients with acute cardiogenic pulmonary edema do not have total body salt and water excess, the judicious use of diuretics is recommended. Often, filling pressures normalize with the use of vasodilators alone. Patients without chronic exposure to loop diuretics usually respond to 20 to 40 mg of intravenous furosemide. Patients undergoing long-term furosemide therapy typically need an intravenous bolus dose at least equivalent to their oral dose. Rather than an arbitrary therapeutic goal of net fluid balance or an estimated dry weight, frequent clinical assessments of volume status should

guide therapy and define the point at which conversion to an oral maintenance regimen should occur. Nevertheless, up to 30% of patients with AHFS continue to have symptoms of congestion at the time of discharge. Important adverse effects include hypotension, hypokalemia, hypomagnesemia, and hypocalcemia. There is also extensive evidence suggesting that intravenous diuretics may result in at least transient neurohormonal activation which is theoretically disadvantageous. Electrolyte repletion is best achieved with scheduled doses of potassium and magnesium supplements to prevent severe deficits. Results of the recently published Diuretic Optimization Strategies Evaluation (**DOSE**) trial demonstrate no benefit of continuous or bolus dose intravenous diuretic administration and no detriment from high doses (an intravenous dose 2.5 times the patients' chronic oral dose of furosemide). If a continuous diuretic infusion is opted for, it should be preceded by a bolus dose, as should any subsequent titration in the continuous rate. Diuretic resistance can be addressed with escalating doses of loop diuretics and subsequently with the addition of a thiazide diuretic (hydrochlorothiazide, metolazone, or chlorothiazide). Some degree of worsening renal function must often be tolerated in order to achieve adequate decongestion. However, if progressive renal failure occurs despite persistent congestion, ultrafiltration or the addition of an intravenous vasodilator or inotrope needs to be considered.

5. **Inotropic therapy.** When signs and symptoms of decompensated heart failure persist despite administration of vasodilators and diuretics, intravenous inotropes may be considered. Their use should be restricted to patients with clear clinical or direct hemodynamic evidence of refractory elevated filling pressures and reduced cardiac output. For patients without significant hypotension, the intravenous inodilators dobutamine or milrinone can be used to augment cardiac output. Both drugs are associated with increased myocardial oxygen demand and cardiac arrhythmias and should be used with extreme caution in patients with ischemia and preexisting arrhythmias. Both drugs may cause hypotension, although this is more common with loading doses of milrinone. ***There is no evidence to support benefit with the use of chronic or intermittent infusion of inotropic agents, and in fact, there is extensive observational data suggesting a trend toward increased postdischarge mortality.*** Use is typically confined to the acute care setting and as a bridge to transplant/mechanical circulatory support or palliation in patients who are not candidates for advanced therapies. In cases of severe hypotension (especially as a result of administration of vasodilators or β-blockers), temporary use of vasopressors such as dopamine, norepinephrine, and phenylephrine may be necessary. In contrast to the conventional wisdom, recent prospective data suggest that norepinephrine is not inferior to dopamine in the setting of cardiogenic shock.
   a. **Dobutamine** acts on β-1 and to a lesser extent on β-2 and α-1 adrenergic receptors. It has a shorter half-life than milrinone and usually is the drug of choice in the acute setting. Infusions are usually started at 2.5 to 5.0 μg/kg/min. On the basis of hemodynamic response, it may be titrated by 1 to 2 μg/kg/min every 30 minutes until the desired effect or a dosage of 10 μg/kg/min is reached.
   b. **Milrinone** is a PDE inhibitor that increases myocardial inotropy by inhibiting the degradation of cyclic adenosine monophosphate. It is a potent systemic and pulmonary vasodilator due to its effects on vascular PDE. For patients who need an immediate inotropic response, a loading dose of 50 μg/kg over 10 minutes is followed by an infusion of 0.125 to 0.75 μg/kg/min. Because it does not target β-receptors, milrinone may be more effective than dobutamine in the setting of recent or ongoing β-blocker therapy.
6. **Ultrafiltration** has been used as an alternative to pharmacologic diuresis in acute decompensated heart failure. The Ultrafiltration vs. Intravenous Diuretics

for patients hospitalized for Acute Decompensated Congestive Heart Failure (**UNLOAD**) study demonstrated that ultrafiltration was safe and resulted in a reduced need for intravenous diuretics and inotropes. Whether ultrafiltration should be considered a first-line alternative to standard intravenous diuretics will depend on the outcome of future trials assessing the relative safety, efficacy, and cost-effectiveness. Currently the use of ultrafiltration is reserved for patients refractory to intravenous diuretic therapy or with diuresis complicated by worsening renal function.

7. **Vasopressin antagonists.** The oral vasopressin receptor 2 antagonist tolvaptan was shown to be safe and results in short-term symptom improvement in patients hospitalized with acute decompensated heart failure in the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (**EVEREST**) trial. This occurred without a reduction in long-term heart failure morbidity or mortality. Tolvaptan and the nonselective intravenous vasopressin receptor inhibitor conivaptan are both approved for the management of hypervolemic or euvolemic hyponatremia that can accompany decompensated heart failure.
8. **Temporary mechanical circulatory support.** The use of temporary and permanent mechanical circulatory support is described in detail in Chapter 12. Patients with refractory cardiogenic shock and cardiogenic pulmonary edema may benefit from the temporary use of intraaortic balloon counterpulsation or an alternative temporary means of mechanical circulatory support (i.e., veno-arterial extracorporeal membrane oxygenation, Impella, or TandemHeart) may facilitate bridging to stabilization or further decision making.
9. Diagnosis and management of atrial and ventricular tachyarrhythmias is critical to the care of patients with acute decompensated heart failure, as these frequently precipitate exacerbations and alter the disease course. Their management is discussed in detail in Chapter 21.
10. **Transition to chronic pharmacotherapy** is implemented once clinical stability is achieved. Generally, vasodilators (ACE inhibitors, angiotensin II receptor blockers [ARBs], or hydralazine/isosorbide dinitrate) are reintroduced first in concert with weaning of intravenous vasodilators. If β-blockers were held due to cardiogenic shock, they can be cautiously reintroduced in stable, euvolemic patients.

B. Chronic medical therapies. The goals of chronic medical therapy are to prolong survival and to improve symptoms and functional status. While there have been few recent major advancements in pharmacotherapy, the evolution of therapies with profound survival benefit for patients with heart failure represents a triumph of modern medicine.

1. **ACE inhibitors** have been shown to reduce morbidity and mortality among patients with systolic heart failure. The mechanism of long-term benefit is related to attenuation of the RAS. In addition, ACE inhibitors improve symptoms, clinical status, and exercise capacity.
   a. **Use of an ACE inhibitor is the first-line therapy for asymptomatic and symptomatic LV dysfunction.** The dose of the ACE inhibitor should be increased to the target doses demonstrating clinical benefits in trials (Table 8.4). Although there are theoretical benefits of using "tissue" ACE inhibitors (e.g., quinapril and ramipril), there are no data to support their preferential use. Relative contraindications include hyperkalemia (potassium > 5.5 mEq/L), renal insufficiency (creatinine > 3.0 mg/dL), and hypotension (systolic blood pressure < 90 mm Hg) and should be gauged on a case-by-case basis. It is not advisable to stop ACE inhibitors in patients with systolic heart failure, even when there is complete resolution of symptoms.

TABLE 8.4 Drug Dosing for Common Medical Therapies for Chronic Heart Failure

Drug	Start (mg)	Target (mg)	Max (mg)
ACE inhibitors			
Captopril (Capoten)	6.25–12.5 tid	50 tid	100 tid
Enalapril (Vasotec)	2.5–5 bid	10 bid	20 bid
Lisinopril (Prinivil, Zestril)	2.5–5 qd	20 qd	40 qd
Ramipril (Altace)	1.25–2.5 bid	5 bid	10 bid
Quinapril (Accupril)	5 bid	20 bid	20 bid
Fosinopril (Monopril)	2.5 or 5 bid	20 bid	20 bid
Benazepril (Lotensin)[a]	2.5 or 5 bid	20 bid	20 bid
Moexipril (Univasc)[a]	7.5 qd	30 qd	30 qd
Trandolapril (Mavik)	1 qd	4 qd	4 qd
Angiotensin receptor blockers			
Candesartan (Atacand)	16 qd	32 qd	32 qd
Valsartan (Diovan)	80 qd	160 qd	320 qd
Losartan (Cozaar)[a]	12.5–25 qd	50 qd	100 qd
Irbesartan (Avapro)[a]	150 qd	300 qd	300 qd
Telmisartan (Micardis)[a]	40 qd	80 qd	80 qd
Hydralazine/isosorbide dinitrate			
Hydralazine	25 qid	50–75 qid	100 qid
Isosorbide dinitrate	10–20 tid	20–80 tid	80 tid
Hydralazine–isosorbide dinitrate (BiDil)	25/37.5 tid	50/75 tid	50/75 tid
Aldosterone antagonists			
Spironolactone (Aldactone)	12.5–25 qd	25 qd	50 bid
Eplerenone (Inspra)	25 qd	50 qd	100 qd
Diuretics[b]			
Furosemide (Lasix)	10 qd (IV) 20 qd (po)	As required	1,000 qd (IV) 240 bid (po)
Bumetanide (Bumex)	1 qd	As required	10 qd
Torsemide (Demadex)	10 qd	As required	200 qd
Ethacrynic acid (Edecrin)	50 qd	As required	200 bid
Hydrochlorothiazide (HCTZ)	25 qd	As required	50 qd
Triamterene (Maxzide)	50 qd	As required	100 bid
Metolazone (Zaroxolyn)	2.5 qd	As required	10 qd

TABLE 8.4 Drug Dosing for Common Medical Therapies for Chronic Heart Failure (*Continued*)

Drug	Start (mg)	Target (mg)	Max (mg)
β-Blockers			
Carvedilol (Coreg)	3.125 bid	25 bid	50 bid
Carvedilol phosphate (Coreg CR)	10 qd	40 qd	80 qd
Metoprolol succinate (Toprol XL)	25 qd	150–200 qd	200 qd
Bisoprolol (Zebeta)[a]	1.25 qd	10 qd	20 qd

ACE, angiotensin-converting enzyme.

[a]Not yet approved by the FDA for management of heart failure.

[b]Oral to IV conversion for furosemide is approximately 2:1. Oral to IV conversion for all other loop diuretics is 1:1.

b. After initiation, close monitoring for **hyperkalemia** and **renal insufficiency** is warranted.

(1) Hypotension is common, especially with first dose in a volume-depleted patient (e.g., after aggressive diuresis). This may require downtitration of diuretic doses and other vasodilator therapy. Due to its short half-life, captopril is usually used in the acute setting (e.g., after myocardial infarction).

(2) Renal insufficiency and **hyperkalemia** may occur when ACE inhibitors are given in the setting of volume depletion. **It is crucial to discontinue other nephrotoxic agents (e.g., nonsteroidal anti-inflammatory agents)** and ensure adequate kidney perfusion. **If BUN or creatinine levels increase by < 50%, ACE inhibitors can be continued safely; if they increase by > 50%, the ACE inhibitor dose should be halved; if they increase by > 100%, the ACE inhibitor should be held and switched to hydralazine and isosorbide dinitrate**. In the case of hyperkalemia, discontinuation of potassium supplementation and reducing the ACE inhibitor dose is usually effective.

c. Unique side effects of ACE inhibitors are cough and angioedema.

(1) The **cough** associated with ACE inhibitors is related to increased levels of bradykinin. It tends to be nonproductive and involuntary, rarely resolving with altering the dose or specific agent. All attempts should be made to identify an alternative cause of cough before discontinuing ACE inhibitors.

(2) Angioedema is a rare complication of ACE inhibitors (0.4%). It involves soft tissue edema of the lips, face, tongue, and, occasionally, the oropharynx and epiglottis. Angioedema typically begins within 2 weeks of initiation of ACE inhibitor therapy, but some patients present with this complication months to years after starting therapy. **Angioedema is an absolute contraindication to the use of any type of ACE inhibitor**.

2. Angiotensin II receptor blockers are specific receptor antagonists to the angiotensin II type 1 receptors. Although they theoretically provide more complete inhibition of the deleterious effects of angiotensin II than do ACE inhibitors, clinical trials have not demonstrated superiority in patients with heart failure. In general, ARBs are used and monitored in the same manner as ACE inhibitors. These drugs are reserved for patients who are ACE inhibitor intolerant, although in practice, they are used extensively. ARBs have a similar side-effect profile to ACE inhibitors (e.g., hypotension, renal insufficiency, and hyperkalemia). There appears to be a < 10% incidence of cross-reactivity for ACE inhibitor–associated

angioedema in patients receiving ARBs. However, consideration for the use of these agents must be weighed against the life-threatening nature of this complication. Whether ARBs can produce additional benefit when added to ACE inhibitors is still being debated. While the addition of an ARB is reasonable in patients on maximal medical therapy including target doses of ACE inhibitors and β-blockers with persistent symptoms, it is preferable to add an aldosterone antagonist in this setting. ARBs should not be added to an ACE inhibitor in the postmyocardial infarction period. Valsartan and candesartan are the best studied ARBs in patients with heart failure and should be used preferentially.

3. The combination of **hydralazine** and **isosorbide dinitrate** may provide a reduction in morbidity and mortality in selected heart failure patients. A fixed dose combination of hydralazine and isosorbide dinitrate (BiDil) demonstrated a substantial reduction in mortality when added to African American patients on optimal medical therapy including ACE inhibitors and β-blockers in the African-American Heart Failure Trial (A-HeFT). This combination is also indicated in patients intolerant of ACE inhibitors or ARBs. Side effects of hydralazine may include reflex tachycardia and rarely drug-induced lupus erythematosus.
4. **β-Adrenergic blockers (β-blockers).** Once considered to be contraindicated in patients with heart failure, β-blockers are now considered **first-line therapy for symptomatic patients with heart failure (NYHA class II, III, or stable class IV)** because of their consistent mortality benefits.
   a. It is often customary to start ACE inhibitors before β-blockers. This in part reflects the fact that all major β-blocker trials demonstrated their benefit on a background of therapy with ACE inhibition. Furthermore, while ACE inhibitors provide immediate beneficial hemodynamic effects, β-blockers may acutely result in diminished LVEF and cardiac output, which may be poorly tolerated in decompensated patients. In some instances (e.g., postmyocardial infarction and comorbid tachyarrhythmias), β-blockers may be particularly beneficial and should be started before or concurrently with ACE inhibitors. β-Blockers should generally not be initiated or titrated in the setting of acutely decompensated heart failure whether due to congestion or severely impaired cardiac output.
   b. Only carvedilol, bisoprolol, and metoprolol succinate have been approved for the medical treatment of chronic heart failure. Although atenolol and metoprolol tartrate are widely available and relatively inexpensive, there is no evidence to support their use in this population. β-Blockers with intrinsic sympathomimetic activity (pindolol and acebutolol) in particular should be avoided.
   c. Relative contraindications to β-blocker therapy are a heart rate < 60 bpm, symptomatic hypotension, more than minimal pulmonary or systemic congestion, signs of peripheral hypoperfusion, a PR interval > 0.24 seconds, second- or third-degree AV block, a history of severe reactive airway disease, and peripheral arterial disease with resting limb ischemia. It is important to note that these are relative contraindications and particularly in the setting of reactive airway disease and peripheral arterial disease, the risks of β-blocker therapy must be weighed against their known benefits.
   d. Current recommendations are to start β-blockers in those who are clinically euvolemic. The general principle is to "start low and go slow." The initial dose is **slowly up-titrated every 2 to 4 weeks over 3 to 4 months to achieve target doses**, provided that the patient can tolerate side effects. It is imperative to maintain contact with the patient and adjust vasodilator or diuretic therapy during titration. It is not advisable to stop β-blockers in patients with a history of heart failure, even if there is complete resolution of symptoms and LV dysfunction.

e. Every effort should be made to achieve target doses, but it is clear that even low doses of these drugs provide benefit. While the degree of β-blockade appears to be the best predictor of long-term response, there is no evidence to support titration to a given resting heart rate.

f. Side effects are common when using β-blockers. Patients should understand that these drugs are used to prolong survival and often do not improve symptoms.

(1) Dizziness and **light-headedness** are common and may be related to hypotension or heart block. **Significant bradycardia** mandates dose reduction of β-blockers and other rate-lowering agents such as digoxin and amiodarone. **Advanced heart block** is a contraindication to β-blockers unless a permanent pacemaker is present. **Hypotension** can be managed by staggering the timing of drug administration. In practice, carvedilol (with its nonselective, α_1-blocking vasodilator effects) may have greater blood pressure lowering than selective β_1 agents such as metoprolol succinate. Both drugs are well tolerated in up to 70% of heart failure patients in our clinics.

(2) Worsening heart failure is still an important adverse effect of β-blockers. Intensification of diuretic therapy and dose reduction or slower titration may be necessary.

5. Aldosterone receptor antagonists have long been used as weak, potassium-sparing diuretics in patients with heart failure. The concept of incomplete blockade of the RAS by ACE inhibitors led to studies demonstrating significant pleiotropic effects of aldosterone antagonism in patients with advanced heart failure including antifibrotic effects and a reduction in sudden cardiac death. Results from the Randomized Aldactone Evaluation Study (**RALES**), Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (**EPHESUS**), and now Eplerenone in Patients with Systolic Heart Failure and Mild Symptoms (**EMPHASIS-HF**) trial have demonstrated substantial mortality benefit in all stages of heart failure.

a. Aldosterone inhibitors are indicated in patients with NYHA class II symptoms and an LVEF ≤ 30% or NYHA class III or IV patients with an LVEF ≤ 35% already treated with ACE inhibitors and β-blockers and without significant renal dysfunction (creatinine > 2.5 mg/dL) or hyperkalemia (potassium > 5 mEq/L). Their use is also indicated in patients with postinfarction LV dysfunction (LVEF ≤ 40%) with any heart failure symptoms or diabetes mellitus.

b. In most cases, potassium supplementation should be reduced or discontinued. A basic metabolic panel should be checked within 1 week after initiation and monitored at regular intervals.

c. The most common and life-threatening side effect of aldosterone antagonists is **hyperkalemia**, which is particularly problematic in patients with concomitant **renal insufficiency** and diabetes mellitus (type IV renal tubular acidosis). **Painful gynecomastia** and **galactorrhea** may occur when using spironolactone.

d. While studies were typically performed with either spironolactone (RALES) or eplerenone (EPHESUS and EMPHASIS-HF), most experts believe that aldosterone inhibitors work via a class effect. Our approach is to initiate treatment with spironolactone due to its low cost and to transition to eplerenone only in the setting of significant gynecomastia.

6. Diuretics are used to maintain euvolemia and to improve symptoms, but their overuse can result in volume contraction, hypotension, and renal dysfunction.

a. An effective and inexpensive initial regimen includes 20 to 120 mg of furosemide taken orally each day. If furosemide doses higher than 120 mg/d are

needed, a second evening dose is typically prescribed. If this regimen fails, a daily dose of a thiazide diuretic such as metolazone or hydrochlorothiazide can be added 30 minutes prior to furosemide dosing.

   b. More expensive loop diuretics (e.g., torsemide and bumetanide) may have superior bioavailability and may be more effective in diuretic-resistant patients. Torsemide in particular may have unique benefits in the form of antifibrotic effects and minimization of the postdiuretic sodium retention that complicates the use of loop diuretics with shorter half-lives.

   c. The concept of **diuretic resistance** is evolving. Very often, this is contributed to by a failure to adhere to a low-sodium (< 2,000 mg/d) diet.

   d. The goal of chronic diuretic therapy is maintenance of euvolemia. This is most reliably achieved in patients who record daily weights and make physician-supported changes in diuretic dosing on an as-needed basis.

7. **Digoxin** is reasonable to use in patients with persistent heart failure symptoms despite appropriate medical therapy including ACE inhibitors and β-blockers and in patients with atrial fibrillation to control ventricular rate.

   a. Despite a fairly narrow therapeutic window, digoxin is safe and significantly reduces heart failure hospitalizations. A typical starting dose of 0.125 mg of digoxin daily is appropriate in patients with normal renal function.

   b. While the **Digitalis Investigation Group (DIG) trial** demonstrated the best clinical outcomes in patients with a serum digoxin concentration of 0.5 to 0.8 ng/mL, routine measurement of levels is not recommended in the absence of concern for toxicity.

8. **Other drugs of importance. Statins** should be used in the secondary prevention of atherosclerotic cardiovascular disease without regard to the presence of heart failure. There is no evidence of benefit in heart failure patients without coronary artery disease. While **aspirin** clearly prevents reinfarction and other vascular events in patients with known coronary artery disease, there is growing evidence from observational and randomized studies that it may worsen outcomes in heart failure patients via inhibition of prostaglandin synthesis and the resultant adverse hemodynamic and renal effects. This remains a controversial subject and the decision of whether to use aspirin or not should be made on a case-by-case basis. It should likely be avoided in patients without coronary disease who have refractory heart failure symptoms.

9. **Electrolyte supplementation** is among the most important and least emphasized areas in chronic heart failure management. Potassium depletion is common with diuretic therapy, whereas hyperkalemia can be caused by ACE inhibitors, spironolactone, or worsening renal insufficiency. In general, oral potassium supplementation is necessary to maintain serum potassium level in the ideal range of 4.0 to 5.0 mEq/L. Magnesium, thiamine, and calcium depletion are also common with long-standing diuretic therapy.

10. **Device therapy.** Chapters 55 and 56 provide detailed coverage of the indications, contraindications, and clinical issues related to implantable cardioverter defibrillators (ICD) and cardiac resynchronization therapy (CRT-D).

11. **Device monitoring.** Currently implanted electrical cardiovascular devices including ICD and CRT-Ds have the capability to remotely monitor a variety of electrophysiologic (e.g., heart rate variability, atrial arrhythmia burden and rate, ventricular tachycardia, % biventricular pacing, and average heart rate) and physiologic (e.g., patient activity and intrathoracic impedance) parameters with prognostic value. Several implantable hemodynamic monitors are under development for use in patients with advanced heart failure. How to best integrate device monitoring into a comprehensive approach to heart failure disease management remains to be established.

12. **Novel therapies**
    a. **ω-3 polyunsaturated fatty acids (PUFA)** have demonstrated an ability to reduce heart failure–associated morbidity and mortality and are now considered a reasonable intervention in patients with NYHA functional class II–IV symptoms by the Heart Failure Society of America. The **Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico Heart Failure (GISSI-HF)** trial demonstrated that 1 g/d of PUFAs resulted in a reduction in all-cause mortality. Recent data suggest that higher doses of PUFAs used in patients with milder heart failure symptoms due to nonischemic cardiomyopathy may result in a dramatic reduction in heart failure hospitalizations. The formulation of PUFA used is important, as there does appear to be a dose–response effect. Formulations containing at least 1 g of eicosapentaenoic acid and docosahexaenoic acid appear to be required for benefit.

C. Chronic nonmedical therapies

1. **Patient education and disease management programs** remain the most effective treatment strategy for patients with systolic heart failure. Sodium restriction (< 2,000 mg daily) and medication compliance are crucial to reducing hospitalizations. Control of blood pressure, serum glucose, and lipid levels should be emphasized. Some highly motivated patients can perform self-monitoring (i.e., daily weights and symptom assessment) and care (i.e., titration of diuretics) analogous to the chronic management of diabetes.
2. **Exercise training.** There is a clear body of evidence supporting the fact that exercise training improves endothelial function and functional capacity in patients with chronic heart failure. A supervised cardiac rehabilitation program should be advised when available.

D. Advanced therapies. Mechanical circulatory support and orthotopic heart transplantation are therapies currently reserved for patients with ACC/AHA stage D heart failure refractory to other therapies. These are described in detail in Chapters 12 and 13, respectively.

VIII. PROGNOSIS. Heart failure is associated with high rates of morbidity and mortality. In the Framingham Heart study, patients with heart failure had mortality rates four to eight times those of age-matched controls. A patient with NYHA class IV heart failure has a 1-year survival between 30% and 50%—a mortality rate comparable to that of advanced malignancies. Several risk scores have been developed to characterize the risk of heart failure hospitalization and mortality. The Seattle Heart Failure Model is perhaps the most widely used of these and incorporates demographic, clinical, pharmacologic, and laboratory data to provide accurate 1-, 2-, and 3-year survival estimates. Table 8.5 lists some common clinical predictors of poor survival in systolic heart failure.

TABLE 8.5 Common Clinical Predictors of Poor Prognosis in Systolic Heart Failure

- Increased age
- Male gender
- Increased New York Heart Association functional class
- Severely reduced LV ejection fraction (< 25%), extensive cardiac remodeling (LVIDd > 65 mm), or reduced cardiac index (< 2.5)
- Concomitant diastolic dysfunction (particularly irreversible restrictive filling, stage IV diastolic dysfunction)
- Reduced right ventricular function

(Continued)

TABLE 8.5 Common Clinical Predictors of Poor Prognosis in Systolic Heart Failure (*Continued*)

- Atrial fibrillation, elevated average heart rate, and reduced heart rate variability
- Low peak Vo_2 with maximal exercise (14 mL/min/kg), low heart rate response to exercise, increased peripheral chemosensitivity (ventilatory response to hypoxia), and high V_E/Vco_2
- High plasma BNP and N-terminal proBNP levels
- High levels of other cardiac and neurohormonal biomarkers including norepinephrine, renin, arginine vasopressin, aldosterone, endothelin-1, tumor necrosis factor, cardiac troponin T and I, and C-reactive protein
- Anemia
- Markers of reduced tissue perfusion:
  - Low mean arterial pressure
  - Renal insufficiency (creatinine clearance < 60 mL/min)
  - Attenuated response to diuretics and lack of hemodynamic and structural improvement (reverse remodeling) with medical therapy
  - Persistent signs of congestion and fluid retention or failure to normalize filling pressures (PCWP < 16 mm Hg, CVP < 8 mm Hg) with medical therapy
  - Serum sodium < 135 mg/dL
- Cardiac dyssynchrony (QRS > 130 milliseconds, left bundle branch block)
- Depression
- Nocturnal Cheyne-Stokes respiration and obstructive sleep apnea

BNP, B-type natriuretic peptide; CVP, central venous pressure; LV, left ventricular; LVIDd, left ventricular internal dimension at diastole; PCWP, pulmonary capillary wedge pressure.

Heart Failure with Preserved Ejection Fraction and Restrictive Cardiomyopathy

I. INTRODUCTION

A. Epidemiologic studies suggest that nearly one-half of patients with heart failure have a normal ejection fraction; the proportion in those hospitalized has been reported to range from 24% to 55%. The survival of patients with heart failure and preserved ejection fraction was once thought to be better than those with a decreased ejection fraction, but recent evidence suggests similar mortality rates.

Heart failure with preserved ejection fraction (HFpEF) has become the preferred term in the literature. This clinical entity has also been referred to as diastolic heart failure and heart failure with preserved ejection fraction. In this chapter, we focus on HFpEF and provide a brief discussion of the restrictive cardiomyopathies, which are important differential diagnoses in patients presenting with heart failure and a normal ejection fraction.

B. Definition. In the latest consensus document (by the European Working Group), HFpEF is defined as **(1) signs *and* symptoms of congestive heart failure; (2) left ventricular ejection fraction (LVEF) > 50% and a nondilated left ventricle (< 97 mL/m^2); (3) and evidence of elevated left ventricular (LV) filling pressures (Table 9.1)**. The last criterion is fulfilled in one of three ways: (1) invasive hemodynamics (pulmonary capillary wedge pressure [PCWP] > 12 mm Hg or left ventricular end-diastolic pressure [LVEDP] > 16 mm Hg), (2) unequivocal echocardiographic evidence of elevated LV filling pressure (E/e' > 15), or (3) equivocal echocardiographic evidence (E/e' > 8 but < 15) **and** a positive β-natriuretic peptide (BNP) (NT-BNP > 220 pg/mL or BNP > 200 pg/mL).

C. Pathophysiology. Most pathophysiologic abnormalities in patients with HFpEF are related to diastolic function. There are two major determinants of diastolic function: LV relaxation and LV stiffness. LV relaxation relates to the cellular mechanisms involved with actin–myosin crossbridge detachment. This requires intracellular calcium uptake into the sarcoplasmic reticulum, an energy- or adenosine triphosphate (ATP)-dependent process. Thus, ischemia, which would decrease intracellular availability of ATP, would prolong the time required for ventricular relaxation. LV stiffness relates to the compliance of the myocardial tissue. One determinant of this is the extracellular matrix. For example, increase in fibrosis and collage deposition, as in patients with hypertensive heart disease, leads to an increase in LV stiffness. Restrictive cardiomyopathies share a similar pathophysiology, with increased LV stiffness; however, these differ in the pathology underlying the change in ventricular compliance: extracellular amyloid deposition (cardiac amyloidosis); endocardial fibrosis from eosinophilic injury (Loeffler's endocarditis and endomyocardial fibrosis); intracellular lysosomal engorgement with sphingolipids (Fabry's disease); and others.

TABLE 9.1 Diagnostic Criteria for Heart Failure with Preserved Ejection Fraction

Clinical	Signs and symptoms of CHF
Left ventricular size and function	Nondilated (< 97 mL/m^2), EF > 50%
Hemodynamics (one of the following conditions must be met)	1. LVEDP > 16 mm Hg or PCWP > 12 mm Hg 2. E/e' > 15 3. If E/e' > 8 but < 15, then BNP must be elevated (NT-BNP > 220 pg/mL or BNP > 200 pg/mL)

CHF, congestive heart failure; EF, ejection fraction; LVEDP, left ventricular end-diastolic pressure; PCWP, pulmonary capillary wedge pressure; BNP, β-natriuretic peptide.

A number of other pathophysiologic mechanisms have been implicated in patients with HFpEF. These include arterial stiffness, the relationship between arterial and ventricular stiffness, and chronotropic incompetence. The implications and relative importance of these mechanisms are still unclear.

II. CLINICAL PRESENTATION

A. Demographics. When compared with patients with systolic dysfunction, those with HFpEF tend to be older and are more likely to be female. Associated comorbidities include hypertension, diabetes, obesity, and chronic kidney disease.

B. Symptoms. Analogous to systolic dysfunction, diastolic dysfunction spans the spectrum of asymptomatic or subclinical disease to those with an established clinical syndrome of congestive heart failure. The symptoms of diastolic heart failure are indistinguishable from those of systolic heart failure. It may present with only exertional fatigue or dyspnea symptoms. Other patients will have more overt symptoms of left-sided (dyspnea, orthopnea, and paroxysmal nocturnal dyspnea) and right-sided (edema and abdominal bloating) heart failure.

C. Signs. The signs of HFpEF are similar to those for systolic heart failure. One should look for the typical signs of right-sided (elevated jugular venous pressure, hepatic congestion, ascites, and lower extremity edema) and left-sided (rales) congestion. The presence of an S4 usually signifies a stiff left ventricle. As opposed to those patients with dilated cardiomyopathies, the location of the apical impulse is usually close to the midclavicular line, signifying a normal-sized ventricle. One should also pay attention to the strength of the impulse; in patients who do not have thick chest walls, a hypertrophied ventricle will often have a stronger impulse than the one without left ventricular hypertrophy (LVH). In patients with exertional symptoms alone, the above signs may not be present as the manifestation of their diastolic dysfunction may occur only during exercise.

In patients who present with impressive right-sided heart failure features, particularly ascites and hepatic congestion, restrictive cardiomyopathy or constrictive pericarditis or a combination should be considered. In these patients, clinical findings of multiorgan disease may indicate specific etiologies of restrictive cardiomyopathy. The cardiac examination may demonstrate more specific findings, including Kussmaul's sign: a paradoxical elevation in the mean jugular venous pressure during inspiration. This is classically described in constrictive pericarditis but can be seen in patients with restrictive cardiomyopathy as well as other pathologies (severe right ventricular failure and tricuspid regurgitation).

III. LABORATORY EXAMINATION AND BASIC INVESTIGATIONS

A. Electrocardiogram (ECG). ECG is an insensitive test for HFpEF. In this scenario, the most important finding is the amplitude of QRS voltage. The presence of elevated voltages and other criteria for LVH would support this as a possible cause of HFpEF. Conversely, in a patient who has increased wall thickness (typically by echocardiography) but has low voltage or infarction patterns on ECG (in this case, "pseudoinfarction"), infiltrative or restrictive cardiomyopathy should be considered.

B. Chest radiograph. The chest x-ray has few specific findings for HFpEF. In a posterior–anterior film, a normal-sized heart (lateral heart width < 2/3 of a hemithorax) may be a clue to a normal-sized left ventricle. Otherwise, the findings are the same as in systolic dysfunction: fluffy alveolar opacities (alveolar pulmonary edema), increased interstitial markings (increased interstitial fluid), pulmonary vascular redistribution (increased pulmonary venous pressures), and pleural effusions.

C. Specific laboratory investigations. BNP can be helpful in establishing the diagnosis of HFpEF (as stated above). When compared with patients with systolic heart failure, the elevation in BNP is generally lower. In patients with undifferentiated dyspnea, a normal BNP would argue against the presence of any heart failure syndrome.

IV. DIFFERENTIAL DIAGNOSIS.

For the purposes of our discussion, there are two clinical presentations to consider: exertional dyspnea (without findings of heart failure) and congestive heart failure. In a patient presenting primarily with exercise intolerance or exertional dyspnea, HFpEF should be considered, in addition to silent coronary artery disease, primary lung disease, anemia, etc.

In a patient who has an established clinical syndrome of heart failure, the differential diagnosis is typically narrowed following echocardiography. In a patient with preserved ejection fraction and a normal-sized left ventricle, HFpEF is the most likely cause. Other entities to consider include restrictive cardiomyopathies, hypertrophic cardiomyopathy (HCM), valvular heart disease, and constrictive pericarditis. Here, we primarily discuss HFpEF and restrictive cardiomyopathies.

A. HFpEF. Heart failure without another obvious cause, particularly in the context of advanced age, hypertension, obesity, chronic kidney disease, and diabetes, should lead to an early consideration for HFpEF. In such patients, myocardial ischemia may play some role in the manifestation of heart failure. This is particularly true for patients presenting with acute heart failure or flash pulmonary edema. In the absence of dynamic valvular regurgitation, ischemia leading to pulmonary edema usually denotes a large amount of myocardium at risk. This type of presentation certainly warrants aggressive investigation for obstructive coronary disease and when applicable, revascularization. Whether or not ischemia plays a role in patients with more subacute or chronic heart failure presentations is debatable.

B. Hypertrophic cardiomyopathy. The diagnosis of HCM is usually made in the presence of LVH, without concomitant hypertension or aortic stenosis. There are many manifestations of HCM, one of which is a "restrictive" phenotype that presents predominantly with diastolic heart failure. Distinction between HCM and other restrictive cardiomyopathies is not always clear, but it should be considered in certain scenarios: examples of this would include family members with HCM (particularly with an identified gene mutation), the typical reverse curve morphology of the interventricular septum, predilection for sudden death or ventricular tachyarrhythmia, and/or the presence of LV outflow tract obstruction.

C. Restrictive cardiomyopathies. Restrictive cardiomyopathies represent a group of disorders in which ventricular stiffness is increased by mechanisms/pathologies other than those related to the more garden-variety HFpEF patients. This may be a result of infiltrative, inflammatory, or metabolic diseases. The most common etiology of restrictive cardiomyopathy is cardiac amyloidosis.

1. **Cardiac amyloidosis.** Amyloidosis refers to the deposition of amyloid, or an abnormal protein, in organ tissue. There are several causes, and the following are the most important ones that manifest with cardiac involvement.
   a. Primary amyloidosis is caused by a primary hematologic malignancy. Monoclonal plasma cells produce a light-chain immunoglobulin; deposition into cardiac tissue is variable. Early stages show subclinical diastolic dysfunction (usually seen on echocardiography); later stages show severe restrictive cardiomyopathy. Traditionally, patients presenting with heart failure are felt to have a very poor prognosis with limited treatment options. However, anecdotal experience suggests that achieving remission of the malignancy with chemotherapeutics may positively impact patient's heart failure symptoms.
   b. Familial amyloidosis involves the inheritance of a gene that produces a mutant form of transthyretin, a serum protein carrier of thyroxine and retinol. The protein is produced in the liver and is deposited in the kidneys, the heart, and the nerves. Some centers may offer cardiac transplantation to selected patients.
   c. Senile amyloidosis is similar to familial amyloidosis in that it is related to the deposition of a pathologic variant of transthyretin. This usually occurs in older men.
2. **Endomyocardial fibrosis.** Endomyocardial fibrosis occurs in areas close to the equator, such as equatorial Africa, South America, and Asia. It usually affects children and young adults. Histologically it is characterized by granulation tissue, collagen, and extensive connective tissue lining the endocardium. It affects both ventricles (50%), left ventricle (40%), or isolated right (10%) ventricle and is associated with a 2-year mortality rate of up to 50%. Atrial fibrillation, mitral regurgitation, and thromboembolism are common. The response to medical treatment is poor. Endocardial decortication may be beneficial for those with New York Heart Association (NYHA) class III or IV symptoms. This technique has high operative mortality (15% to 20%), but when successful, reduces symptoms and may favorably affect the survival.
3. **Loeffler's (eosinophilic) endocarditis.** Loeffler's endocarditis is more commonly seen in temperate climates and generally occurs as part of the idiopathic hypereosinophilic syndrome. It typically manifests in middle age. Features include eosinophilia, restrictive cardiomyopathy, and nervous system and marrow involvement. Left ventricular mural thrombus frequently occurs. Aside from conventional heart failure medications (including anticoagulation), corticosteroids and hydroxyurea are useful treatment options. Surgery may be required for advanced fibrotic disease.
4. **Idiopathic restrictive cardiomyopathy.** Idiopathic restrictive cardiomyopathy is a diagnosis of exclusion. It usually occurs sporadically, but may be inherited with an autosomal dominant pattern in association with distal skeletal myopathy and occasionally a heart block. Echocardiography reveals near-normal LV dimensions and function, biatrial enlargement, and variable hypertrophy. Endomyocardial biopsy is unremarkable or shows nonspecific changes. The condition may manifest at any age throughout childhood or adult life. Survival time varies, with a mean survival of 9 years. Cardiac transplantation may be indicated in selected patients.
5. **Sarcoidosis.** Cardiac sarcoidosis can present with restrictive cardiomyopathy, but much more commonly it produces a dilated cardiomyopathy phenotype. Associated cardiac manifestations include conduction disease and ventricular tachyarrhythmia.
6. **Radiation carditis.** Radiation heart disease affects almost all components of the heart. Direct myocardial involvement, usually in the form of diastolic dysfunction, can be underappreciated, particularly when there is concomitant valvular, coronary, and/or pericardial disease. Separating the relative contributions of multiple pathophysiologic mechanisms in a given radiation patient is extraordinarily challenging. This is particularly evident when these patients go to surgery for

correction of valvular, coronary, and/or pericardial disease; suboptimal outcomes despite these corrections may be related to residual myocardial disease.

7. **Metabolic storage diseases** are characterized by intracellular deposition of substances within the myocyte, resulting in increased myocardial stiffness.
   a. **Hemochromatosis**, or iron overload, is listed as a storage disorder that can cause restrictive cardiomyopathy. However, when cardiac manifestations occur, the phenotype is usually a dilated cardiomyopathy.
   b. **Glycogen storage diseases.** Types II, III, IV, and V glycogen storage diseases may present with cardiac manifestations, usually as asymptomatic increase in LV thickness.
   c. **Gaucher's disease.** Gaucher's disease is caused by a deficiency in β-glucosidase, which leads to cerebroside deposition into multiple organs (spleen, liver, brain, bone marrow, lymph nodes, and heart). In the heart, this can cause increased ventricular thickness with diastolic dysfunction, LV systolic dysfunction, pericardial effusion, and valvular disease. This can be treated with enzyme replacement.
   d. **Fabry's disease** is a lysosomal storage disease caused by a deficiency in α-galactosidase (X-linked, recessive trait). This leads to glycosphingolipid accumulation in the kidney, the skin, and the heart. Cardiac manifestations include increased LV thickness, diastolic dysfunction, AV block, and mitral regurgitation. This can be treated with enzyme replacement.

V. DIAGNOSTIC TESTING

A. Echocardiography is the primary modality in evaluating a patient with a clinical syndrome of congestive heart failure. It is the modality of choice when evaluating LV diastolic function (Fig. 9.1). The most commonly used parameter in clinical practice is the Doppler interrogation of the transmitral flow pattern and tissue Doppler evaluation of annular velocity to determine the E/e' ratio. There are numerous other 2D and Doppler findings that are critical to diagnosis, including chamber size and wall thickness.

1. **Transmitral flow pattern.** In sinus rhythm, using pulsed wave Doppler across the mitral inflow tract generates two waves: the early E wave, corresponding to rapid ventricular filling as the mitral valve opens, and the A wave, which reflects atrial contraction. In healthy people younger than 50 years, E is larger than A (i.e., E/A ratio > 1). The E-wave deceleration time is the time from peak E inflow

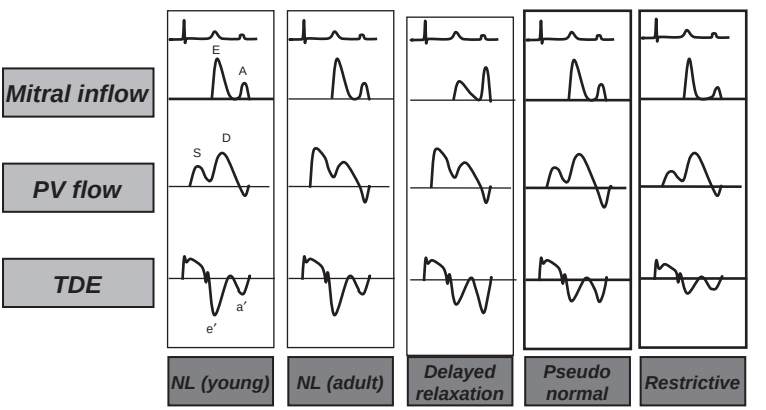

FIGURE 9.1 Patterns of diastolic function. PV flow, pulmonary vein flow; TDE, tissue Doppler (mitral annulus); NL, normal.

velocity to decay to zero. With age, hypertension, or ischemia, the viscoelastic properties of the ventricle decrease, and the E wave decreases in amplitude, has a gentler slope, and has a longer deceleration time. The atrial kick is proportionately greater, and E–A reversal occurs, with an E/A ratio < 1 (grade 1 diastolic dysfunction). With progression of diastolic dysfunction, left atrial (LA) pressure rises further to compensate, and the E wave becomes more prominent than the A wave (i.e., pseudonormalization or grade 2 diastolic dysfunction). As diastolic dysfunction progresses, the LV stiffness increases and the deceleration time shortens, reflecting rapid equilibration of LA/LV pressures during early diastole. When the deceleration time is < 160 milliseconds and the E/A ratio is > 2, the patient is considered to have grade 3 diastolic dysfunction.

Although the transmitral flow pattern is one of the primary ways of evaluating diastolic function, it has several limitations. It can be difficult to differentiate normal diastolic function from the "pseudonormal" pattern of grade 2 diastolic dysfunction, as they both have E/A ratios > 1. Because of this, American Society of Echocardiography guidelines have assigned stronger weight to other findings, including tissue Doppler imaging (TDI) and LA chamber size. Also, the transmitral flow pattern can often be difficult to interpret or uninterpretable in common scenarios, including atrial fibrillation, tachycardia (fusion of E and A waves), and mitral valve disease (MR ≥ 3+, mitral stenosis, and mitral prosthesis).

2. **Tissue Doppler imaging (TDI) of the mitral annular velocity.** In the evaluation of LV diastolic function, TDI is used to measure the velocity of movement of the septal and lateral aspects of the mitral annulus. The myocardial velocities have three main components: systolic wave (S'), early diastolic wave (e'), and the late diastolic wave (a'). In the earliest stages of diastolic dysfunction, the diastolic velocities of annular motion decrease. Normally, the lateral annulus tends to have higher velocities than the septal mitral annulus. Septal e' < 8 cm/s and/or a lateral e' < 10 cm/s suggests the presence of diastolic dysfunction.

   Unlike the transmitral flow pattern, there is no "pseudonormalization" pattern with annular velocity, making it easier to differentiate normal from abnormal diastolic function. The mitral annular TDI should be used with caution when other conditions coexist that may affect annular velocity independent of ventricular relaxation such as infarction of the septum or lateral wall or constriction with pericardial adhesion of the lateral wall.

3. **E/e'.** The ratio of the E velocity (obtained from the transmitral flow pattern) and the e' (obtained from TDI primarily of the lateral mitral annulus) can be used to estimate filling pressure, as there is a rough correlation with invasive hemodynamics (PCWP). This correlation is better with patients with depressed ejection fraction but is reasonable in patients with normal ejection fraction. Extreme values are most helpful. E/e' < 8 correlates with normal LV filling pressures. E/e' > 15 correlates with PCWP > 12 mm Hg; higher values are more specific for this. Unfortunately, there are many patients that fall into the intermediate zone, where E/e' > 8 but < 15. For these patients, the presence of elevated filling pressure cannot be determined by this method alone. Echocardiographic guidelines suggest using the presence of LA enlargement (LA volume index > 34 mL/m^2). Plasma BNP may be helpful in equivocal cases to determine whether or not there is corroborating evidence for elevated pressures.

   In patients with predominantly **exertional** symptoms, it may be useful to perform exercise echocardiography to determine the presence of diastolic dysfunction during exertion, particularly when this is not evident at rest. The sonographer should obtain LV images in multiple views following stress. Once the 2D information has been acquired, Doppler studies, including the transmitral flow pattern and the TDI of the septal and lateral mitral annulus, should be recorded. The diastolic abnormalities usually persist after tachycardia subsides, so

it is recommended that the data are recorded for a period of time following stress to reduce the likelihood of E- and A-wave fusion, which would make the E-wave velocity difficult to interpret. The most important parameter is E/e' following stress; if it is > 15, exertional increase in LV filling pressures is likely.

B. Invasive hemodynamic assessment. Invasive hemodynamic assessment is not routinely performed but is indicated when it is unclear whether elevated filling pressures are present on noninvasive studies. The PCWP (> 12 mm Hg) or LVEDP (> 16 mm Hg) should be measured. Other diastolic parameters, including Tau (τ), the time constant of isovolumic relaxation, are rarely measured in clinical practice.

When restrictive cardiomyopathy is considered, detailed hemodynamics may be of greatest value in directing management but are often less helpful in differentiating between possible diagnoses. Findings such as elevated and equalized diastolic pressures in four chambers (within 5 mm Hg), M pattern of the right atrial pressure waveform, "dip and plateau" of the ventricular diastolic pressures, equalization of LVEDP/RVEDP, and Kussmaul's sign occur in a number of pathologies, including restrictive cardiomyopathy, constrictive pericarditis, severe right ventricular failure, and severe tricuspid regurgitation.

C. Magnetic resonance imaging (MRI). In most patients with a diagnosis of HFpEF, cardiac MRI is rarely needed. It is useful to measure ventricular function, mass, and volumes when echocardiography is not diagnostic. It is also helpful in establishing or excluding specific conditions such as constrictive pericarditis, sarcoidosis, amyloidosis, or hemachromatosis (see Chapter 51).

D. Endomyocardial biopsy. Endomyocardial biopsy is used in selected circumstances, particularly when there is a high suspicion of a disorder whose diagnosis will profoundly impact management and prognosis. The most common indication is when cardiac amyloidosis is suspected. Biopsy in this setting can determine the presence of amyloid as well as differentiate between the different types of amyloid. The yield of endomyocardial biopsy for patchy diseases, such as sarcoidosis, is low.

VI. THERAPY. A handful of trials have attempted to look at the role of a variety of agents, including angiotensin receptor blockers (ARBs), angiotensin-converting enzyme (ACE) inhibitors, and β-blockers in patients with HFpEF. Unfortunately, **none of these trials have shown mortality benefit**. There has been variable effect of these medications on morbidity end points, including heart failure hospitalizations, symptoms, and LVH regression. The relevance of some of these trials is in question, as their entry criteria included patients with LV dilation and LVEF < 50%, likely a population quite different from our current conception of HFpEF patients. As the literature currently stands, no specific treatment has clearly demonstrated mortality benefit in patients with HFpEF. Treatment of hypertension should be in accordance with JNC VII guidelines (the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure). Otherwise, treatment should be aimed toward symptomatic relief. The current ACC/AHA 2009 guidelines are listed in Table 9.2.

A. Salt restriction. Patients should be placed on a salt-restricted diet, usually 2,000 mg of sodium daily.

B. Diuretics. Diuretics should be used for symptomatic treatment of edema and pulmonary congestion. Chronic use of loop diuretics may lead to diuretic resistance; in this scenario, a thiazide- or potassium-sparing diuretic may be used to augment diuresis. For this indication, hydrochlorothiazide (usually 50 mg dosage, given once or intermittently) is effective within the first day. In extreme cases, patients may have significant bowel edema, rendering diuretics with poor oral absorption ineffective. In these patients, torsemide, which has a better oral absorption profile, is a reasonable option. Diuresis is often limited by the occurrence of prerenal azotemia. This is particularly common in those HFpEF or restrictive cardiomyopathy patients with

TABLE 9.2 Guidelines Adapted from ACC/AHA 2009 Update

Class I guidelines	
Control systolic and diastolic hypertension	Physicians should control hypertension in accordance with published guidelines (level of evidence: A)
Diuretics	Physicians should use diuretics to control pulmonary congestion and peripheral edema (level of evidence: C)
Ventricular rate should be controlled in the presence of AF	Physicians should control ventricular rate in AF (level of evidence: C)
Class IIa guidelines	
Coronary revascularization	In patients with CAD in whom ischemia is having an adverse effect on cardiac function (level of evidence: C)
Class IIb guidelines	
Restoration and maintenance of sinus rhythm	May be useful in improving symptoms (level of evidence: C)
Digoxin	Usefulness in reducing symptoms is not well established (level of evidence: C)
β-Blockers, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, or calcium antagonists and controlled hypertension	Might be effective in minimizing symptoms (level of evidence: C)

AF, atrial fibrillation; CAD, coronary artery disease.

systemic disorders that have concomitant effects on the kidney, including hypertension, diabetes, or amyloidosis. In these cases, balancing congestive symptoms and azotemia can be challenging. On occasion, the patient may only achieve symptomatic relief after aggressive diuresis, even to the point where the blood urea nitrogen and/or creatinine are at levels higher than baseline values.

C. Angiotensin receptor blockers. Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity Programme (CHARM-P) and Irbesartan in Heart Failure with Preserved Ejection Fraction Study (I-PRESERVE) are two trials that evaluated the use of ARBs in the HFpEF population. I-PRESERVE is arguably the most relevant trial, as it enrolled patients with LVEF ≥ 45% and randomized patients to irbesartan versus placebo. This trial showed no difference in the primary end point of mortality and heart failure hospitalizations between the active and placebo groups. CHARM-P, which randomized candesartan versus placebo also failed to show a difference in a similar primary end point; the secondary end point of heart failure hospitalizations did seem to be reduced in the candesartan arm.

D. ACE inhibitors. The Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial randomized patients with LVEF > 40% to perindopril versus placebo. The primary end point was not met, but after 1 year, there appeared to be a statistically significant decrease in heart failure hospitalizations in the active treatment arm.

E. Beta-blockers. The Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure (SENIORS) trial randomized

nebivolol versus placebo in all-comers with congestive heart failure. Thirty-five percent of the patients had LVEF > 35%. In the overall trial, the nebivolol group demonstrated a significant decrease in the primary end point of mortality and heart failure mortality. In the subgroup analysis, the improvement appeared to hold in the group with LVEF > 35%.

F. Digoxin. The Digitalis Investigation Group (DIG) trial evaluated the use of digoxin in patients with heart failure. A subgroup of that trial examined patients with LVEF > 45%. There was no significant difference in mortality in this subgroup. There was a nonsignificant trend toward decreased heart failure hospitalizations but an increased trend toward unstable angina hospitalizations in those treated with digoxin.

G. Spironolactone. In patients with depressed ejection fraction, aldosterone antagonists have been demonstrated to have beneficial effects, likely working through antifibrotic mechanisms. There are two ongoing pivotal trials, Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) and Aldosterone Receptor Blockade in Diastolic Heart Failure (ALDO-HF), designed to evaluate the use of spironolactone in patients with HFpEF.

H. Sildenafil. Currently, there is no indication for phosphodiesterase 5 inhibitors in HFpEF, and mechanistic studies are ongoing.

VII. PRACTICAL APPROACH TO HFpEF AND RESTRICTIVE CARDIOMYOPATHIES

A. Exertional dyspnea only. In these patients, HFpEF should be on the differential diagnosis. Resting echocardiogram should be performed, with particular attention paid toward the presence of resting diastolic dysfunction. If this is absent, one can consider exercise echocardiography to determine exercise-induced diastolic dysfunction. Even in the presence of this diagnosis, specific treatment or change in management is uncertain.

B. Congestive heart failure. For patients presenting with overt signs of congestive heart failure, echocardiography should be used to narrow the differential diagnosis. In the absence of findings to support LV systolic dysfunction, valvular disease, or constrictive pericarditis, one should consider HFpEF as the diagnosis if there is evidence of diastolic dysfunction and elevated LV filling pressures. This is determined by unequivocal echocardiographic evidence ($E/e' > 15$); equivocal echocardiographic evidence ($E/e' > 8$ and < 15) + elevated BNP (NT-BNP > 200 pg/mL or BNP > 200 pg/mL); or invasive hemodynamics (PCWP > 12 mm Hg, LVEDP > 16 mm Hg). If the above findings are met and the patient fits the appropriate demographic (elderly, female, hypertension, chronic kidney disease, diabetes, and obese), then HFpEF is a reasonable diagnosis.

Restrictive cardiomyopathy should be entertained when patients present with significant right-sided heart failure symptoms (ascites, hepatic congestion, and severe edema), have multiorgan presentations (amyloidosis—orthostasis and renal failure; Fabry's—renal and skin involvement), or do not fit the typical demographic for HFpEF (young and no hypertension). In these patients, additional, focused testing should be performed to establish the etiologic diagnosis. This may include cardiac MRI and, in selected circumstances, endomyocardial biopsy.

C. Treatment. To date, there has been no class of medications that has been clearly established to have mortality benefit for patients with HFpEF. As it is believed that hypertension is the underlying etiology in most patients with HFpEF, blood pressure in these should be treated according to the established guidelines. However, particular agents do not have a priority as they do in patients with depressed ejection fraction, because they have not yet been demonstrated to have the same mortality and morbidity benefits. Otherwise, diuretics should be used for symptomatic benefit. The importance of concomitant obstructive coronary artery disease is debatable in asymptomatic patients. Likewise, revascularization should be reserved for patients in which ischemia is thought to play a major, adverse role in cardiac function (Table 9.2).

For those patients with restrictive cardiomyopathy, treatment should be directed toward the specific etiology. Oftentimes, there are no therapies that can reverse the severity of the restrictive cardiomyopathy, and the presence of congestive heart failure portends a poor prognosis. In these patients, diuretics are used for symptomatic relief. In selected candidates, cardiac transplantation may be entertained.

VIII. PROGNOSIS. HFpEF was once thought to confer a better prognosis than systolic dysfunction. Recent evidence demonstrates that the survival rates in both cases are similar. Twenty-two percent to 29% of patients with HFpEF die within 1 year of being discharged from their first hospitalization; 65% die within 5 years. Unlike patients with systolic dysfunction, no effective treatment has been found to improve this dismal outcome. The two groups have also been found to have similar rates of readmission for heart failure.

Eiran Z. Gorodeski

Hypertrophic Cardiomyopathy

I. INTRODUCTION. The generally accepted definition of hypertrophic cardiomyopathy (HCM) is left ventricular (LV) hypertrophy associated with nondilated ventricular chambers in the absence of another cardiac or systemic disease that itself could produce such hypertrophy. There are many causes of LV wall thickening (Table 10.1), including long-standing hypertension, aortic stenosis, and infiltrative cardiomyopathies. However, these diseases can typically be identified by noninvasive markers, such as a history of significant hypertension and severe aortic stenosis. Other diseases will be identified by multisystem organ involvement (e.g., skeletal muscle weakness in Danon disease). HCM can be identified by a constellation of abnormalities, including gene mutations, marked LV thickness (> 25 mm), the presence of left ventricular outflow tract (LVOT) obstruction, and/or the presence of systolic anterior motion (SAM).

While there are many alternative names for HCM, including *idiopathic hypertrophic subaortic stenosis, hypertrophic obstructive cardiomyopathy, and muscular subaortic stenosis*, the World Health Organization (WHO) recommends that HCM should be used. It is the preferred term because it does not imply that obstruction (present in only approximately 25% of cases) is an invariable component of the disease.

II. CLINICAL PRESENTATION

A. Natural history

1. The **histological features** of HCM are disarray of cell-to-cell arrangement, disorganization of cellular architecture, and fibrosis. The most common sites of ventricular involvement are, in decreasing order, the septum, apex, and midventricle. One-third of patients have wall thickening limited to one segment. These morphologic and histological features, which vary in phenotypic and clinical expression, give rise to the characteristically unpredictable natural history of HCM.
2. The **prevalence** of HCM is approximately 1 in 500, and the condition appears to be familial in origin. This makes HCM one of the most common genetically transmitted cardiovascular diseases. It is found among 0.5% of unselected patients referred for echocardiographic examination and is a leading cause of sudden death among athletes younger than 35 years.

B. Signs and symptoms

1. **Heart failure.** Symptoms, which include dyspnea, dyspnea on exertion, paroxysmal nocturnal dyspnea, and fatigue, are largely a consequence of two processes: elevated LV diastolic pressure caused by diastolic dysfunction and dynamic LV outflow obstruction.
   a. Events that accelerate heart rate, decrease preload, shorten diastolic filling time, increase LV outflow obstruction (i.e., exercise and tachyarrhythmias), or worsen compliance (i.e., ischemia) exacerbate these symptoms.

TABLE 10.1 Differential Diagnosis of Left Ventricular Wall Thickening

Long-standing hypertension

Friedreich's ataxia
Danon disease
Noonan syndrome
Pompe disease

   b. Between 5% and 10% of patients with HCM progress to severe LV systolic dysfunction, characterized by progressive LV wall thinning and cavity enlargement.

2. **Myocardial ischemia.** Myocardial ischemia occurs in obstructive and nonobstructive HCM.
   a. The **clinical and electrocardiographic** presentation is similar to that of ischemic syndromes in persons without HCM. Ischemia has been demonstrated with thallium perfusion studies, elevated myocardial lactate levels during rapid atrial pacing, and positron emission tomography.
   b. While epicardial artery obstruction is less common, **mismatch of supply and demand** due to thickened vessels and small vessel disease from increased collagen deposition in the intima and media are the most likely pathophysiologies of ischemia. Contributing factors include the following:
      (1) Small vessel coronary disease with decreased vasodilator capacity
      (2) Elevated myocardial wall tension as a consequence of delayed diastolic relaxation time and obstruction to LV outflow
      (3) Decreased capillary-to-myocardial fiber ratio
      (4) Decreased coronary perfusion pressure
3. **Syncope and presyncope** are usually a consequence of diminished cerebral perfusion caused by inadequate cardiac output. These episodes are commonly associated with exertion or cardiac arrhythmia.
4. **Sudden death.** The annual mortality rate for HCM is **1%**. Most deaths are sudden or unexpected.
   a. Not all patients with HCM are at equal **risk for sudden death**. Twenty-two percent of patients with sudden death have no symptoms. **Sudden death appears to be most common among older children and young adults**; it is rare in the first decade of life. Approximately 60% of deaths occur during periods of inactivity; the remaining deaths occur after vigorous physical exertion.
   b. **Arrhythmogenic and ischemic mechanisms** can initiate a clinical spiral of hypotension, decreased diastolic filling time, and increased outflow obstruction that often culminates in death.

III. PHYSICAL EXAMINATION

A. Inspection of the jugular venous system may reveal a prominent *a* wave that indicates hypertrophy and lack of compliance of the right ventricle. A precordial heave, representing right ventricular (RV) strain, can be found in persons with concomitant pulmonary hypertension.

B. Palpation

1. The **apical precordial pulse is usually laterally displaced and diffuse**. LV hypertrophy may cause a presystolic apical impulse or palpable fourth heart sound (S_4). A three-component apical impulse may occur, with the third impulse resulting from a late systolic bulge of the left ventricle.
2. The carotid pulse has been classically described as bifid. This **rapid carotid upstroke followed by a second peak** is caused by a hyperdynamic left ventricle. This is in contrast to the *parvus et tardus* pulse of fixed aortic or subvalvular aortic stenosis, which is a carotid pulse characterized by a delayed amplitude and upstroke.

C. Auscultation

1. S_1 (first heart sound) is usually normal and is preceded by S_4.
2. S_2 (second heart sound) can be normal or paradoxically split as the result of the prolonged ejection time of patients with severe outflow obstruction.
3. The **harsh, crescendo–decrescendo systolic murmur** associated with HCM is best heard at the left sternal border. It radiates to the lower sternal border but not to the neck vessels or axilla.
   a. An important aspect of the murmur is its **variation in intensity and duration** with ventricular loading conditions. During periods of increased venous return, the murmur is of shorter duration and is less intense. In the underfilled ventricle and during periods of increased contractility, the murmur is harsh and of a longer duration.
      (1) The **concomitant murmur of mitral insufficiency** can be differentiated because of its holosystolic, blowing quality that radiates to the axilla.
      (2) A soft, early, decrescendo, **diastolic murmur of aortic insufficiency** is found in approximately 10% of patients with HCM.
   b. **Maneuvers that affect preload and afterload** can be helpful in diagnosing HCM and differentiating it from other systolic murmurs (Table 10.2).

TABLE 10.2 Effects of Maneuvers or Pharmacologic Intervention to Differentiate Murmur of Hypertrophic Cardiomyopathy from Aortic Stenosis

Maneuver	Physiologic effect	HCM	AS	MR
Valsalva and standing	Decreases VR, SVR, and CO	↑	↓	↓
Squat and handgrip	Increases VR, SVR, and CO	↓	↑	↑
Amyl nitrite	Increases VR Decreases SVR and LV volume	↑	↑	↓
Phenylephrine	Increases SVR and VR	↓	↑	↑
Extrasystole	Decreased LV volume	↑	↓	No change
Post-Valsalva release	Increased LV volume	↓	↑	No change

AS, aortic stenosis; CO, cardiac output; HCM, hypertrophic cardiomyopathy; LV, left ventricular; MR, mitral regurgitation; SVR, systemic vascular resistance; VR, venous return; ↓, decrease; ↑, increase.

TABLE 10.3 Molecular Genetics of Hypertrophic Cardiomyopathy

Gene symbol	Protein name	% of HCM caused by mutations in this gene
MYH7	Myosin heavy chain	40
MYBPC3	Myosin-binding protein C	40
TNNT2	Troponin T	5
TNNI3	Troponin I	5
TPM1	Tropomyosin 1	2
ACTC1	Actin, α	Unknown
MYL2	Myosin regulatory light chain 2	Unknown
MYL3	Myosin light polypeptide 3	1

HCM, hypertrophic cardiomyopathy.

IV. GENETIC ASPECTS OF HCM. Familial HCM is caused by mutation in one of the genes currently known to encode different components of sarcomere proteins or sarcomere-associated proteins that are inherited in an autosomal dominant manner (see Chapter 42). To date, familial HCM is known to be caused by over 1,400 different mutations in at least 8 genes (Table 10.3). Multiple analyses suggest that these common genetic subtypes are essentially phenotypically indistinguishable.

HCM genotype does not necessarily imply that subjects will have the phenotypic traits of HCM as variable penetrance exists, and environmental factors as well as modifier genes affect whether a particular subject will manifest HCM phenotypically.

Patients with an **identified pathogenic mutation** are at an increased risk for cardiovascular death, nonfatal stroke, or progression to NYHA functional class III or IV compared with patients with no identified mutations.

V. DIAGNOSTIC TESTING

A. Electrocardiogram (ECG). Although most patients have electrocardiographic evidence of disease, no changes are pathognomonic for HCM. Common electrocardiographic findings in HCM are listed in Table 10.4. These abnormalities do not correlate with disease severity or pattern of hypertrophy.

B. Echocardiography is the preferred diagnostic method because of its high sensitivity and low risk profile. It also allows characterization of the site of obstruction. Careful

TABLE 10.4 Electrocardiographic Findings in Hypertrophic Cardiomyopathy

Evidence of right and left atrial enlargement
Q waves in the inferolateral leads
Voltage criteria for large negative precordial T waves (associated with Japanese variant)
Left-axis deviation
Short PR interval with slurred upstroke

TABLE 10.5 Two-Dimensional, M-Mode, and Doppler Echocardiographic Findings in Hypertrophic Cardiomyopathy

Asymmetric septal hypertrophy (> 13 mm)
Systolic anterior motion of the mitral valve
Small left ventricular cavity
Septal immobility
Premature closure of the aortic valve
Resting gradients > 30 mm Hg
Provocable gradients > 50 mm Hg
Normal or increased motion of the posterior wall
Reduced rate of closure of the mitral valve in mid-diastole
Mitral valve prolapse with regurgitation
Maximal left ventricular diastolic wall thickness > 15 mm

assessment for conditions that can also cause secondary hypertrophy (aortic or subaortic stenosis, hypertension, infiltrative diseases, etc.) should also be done.

1. **M-mode and two-dimensional** echocardiographic findings in HCM are listed in Table 10.5. Close evaluation of the extent of hypertrophy should be done given the role of septal thickness in risk stratification for sudden cardiac death (SCD).
2. **Doppler echocardiography** enables recognition and quantification of dynamic LVOT obstruction as well as the response to various maneuvers.
   - **a.** Approximately one-fourth of patients with HCM have a resting pressure gradient between the body and LVOT; others have only provocable gradients.
   - **b.** The **diagnosis of HCM with obstruction** is based on resting peak instantaneous gradient > 30 mm Hg. These gradients correlate directly with the time of onset and duration of contact between the mitral leaflet and the septum, as occurs during SAM of the mitral leaflet. The earlier and longer the contact occurs, the higher the pressure gradient.
     - **(1)** Inducing obstruction and, therefore, gradients, in patients believed to have latent obstruction, can be accomplished with substances (e.g., amyl nitrite, isoproterenol, and dobutamine) or maneuvers (e.g., Valsalva maneuver and exercise) that decrease LV preload or increase contractility.
     - **(2)** Although the **clinical relevance of outflow obstruction has been debated, relief by means of surgical or pharmacologic technique is associated with clinical improvement** among many patients. Echocardiographic recognition of HCM and of HCM with outflow obstruction is, therefore, important.
   - **c. Recognition of mitral regurgitation (MR).** Echocardiographic evaluation of MR and the detection of valve anomalies may have a considerable effect on medical and surgical strategies in the care of patients with HCM.
     - **(1)** Approximately **60% of patients with HCM have structural abnormalities of the mitral valve**, including increased leaflet area, elongation of leaflets, and anomalous insertion of papillary muscles directly into the anterior mitral leaflet.

(2) When there is no leaflet abnormality, the degree of MR is directly related to the severity of obstruction and lack of leaflet coaptation.

C. Magnetic resonance imaging (MRI). Advantages of MRI in the evaluation of HCM include excellent resolution, lack of radiation, inherent contrast, three-dimensional imaging, and tissue characterization. Disadvantages are cost, length of study, and exclusion of patients with contraindications to exposure to magnetism, such as patients with implantable cardioverter–defibrillators (ICDs) or pacemakers.

1. MRI can detect **LV hypertrophy** missed by echocardiography, specifically in the anterolateral and basal LV free walls.
2. **Myocardial scar**, often found in patients with HCM, can be detected as **delayed hyperenhancement with gadolinium-contrast MRI**. Some small studies have suggested that the amount of hyperenhancement may be a predictor of SCD in this patient population.
3. Improved identification of MR, SAM, abnormal papillary muscles, and diastolic dysfunction.
4. Differentiate from alternative causes of LV thickening such as Fabry disease and amyloidosis.

D. Cardiac catheterization is used primarily for defining coronary anatomy before myectomy or a mitral valve operation and evaluation of ischemic symptoms. The characteristic findings of HCM during hemodynamic assessment are listed in Table 10.6 and illustrated in Figure 10.1.

1. Patients with normal coronary arteries may have **typical ischemic symptoms**. These symptoms may indicate myocardial bridges, phasic narrowing during systole, reduced coronary flow reserve, or systolic reversal of flow in the epicardial vessels.
2. **Left ventriculography** usually reveals a hypertrophied ventricle, prominent septal bulge, nearly complete obliteration of the ventricular cavity during systole, SAM, and MR. The **spadelike** appearance of the ventricular cavity is confined to ventricles with **apical involvement**.

VI. MANAGEMENT STRATEGIES

A. Priority of therapy. Effective therapy must include pathways for the **prevention and management of heart failure** caused by diastolic and systolic dysfunction, arrhythmias, ischemia, and failed medical therapy and the **prevention of sudden death**. The specific strategies for patients with HCM can be as heterogeneous as the clinical presentation and evolution. See Figure 10.2 for a simplified treatment algorithm.

TABLE 10.6 Hemodynamic Findings during Cardiac Catheterization

Subaortic or mid-ventricular outflow gradient on catheter pullback
Spike-and-dome pattern of aortic pressure tracing[a]
Elevated right and left ventricular end-diastolic pressures
Elevated pulmonary capillary wedge pressure
Increased V wave on wedge tracing[b]
Elevated pulmonary arterial pressure

[a]A consequence of outlet obstruction.
[b]May result from either mitral regurgitation or elevated left atrial pressure.

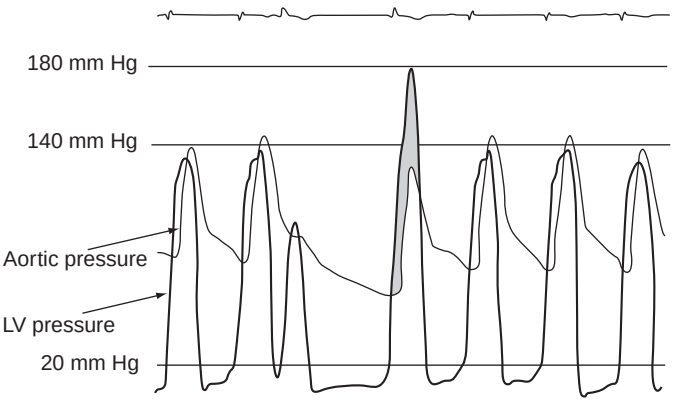

FIGURE 10.1 Severe increase in the left ventricular (LV) aortic gradient in the beat after a premature ventricular contraction (PVC) (Brockenbrough-Braunwald-Morrow sign) due to an increase in contractility and decrease in afterload during the post-PVC beat.

B. Medical therapy. Although never proven to reduce mortality in clinical trials, **β-blockers are the first-line therapy** for HCM, regardless of the presence of LV outflow obstruction.

1. **β-Blockers** improve symptoms and exercise tolerance. β-Blockers with additional α-blocking properties, such as carvedilol and labetalol, should probably not be used as first-line agents because of their additional vasodilatory properties.
   a. The mechanism of action of β-blockers is inhibition of sympathetic stimulation brought about by the negative inotropic and chronotropic properties of the drugs. β-Blockers diminish myocardial oxygen requirements and augment diastolic filling, which mitigate angina and the detrimental effects of LV outflow obstruction, respectively.
2. **Calcium channel blockers (CCBs)** are considered to be second-line agents that are also effective in reducing the common symptoms of HCM in patients who are intolerant of or have undergone unsuccessful treatment with β-blockers.
   a. **CCBs** have a negative inotropic effect and reduce the heart rate and blood pressure. They may also have beneficial effects on diastolic function by improving rapid diastolic filling, although possibly at the expense of higher LV end-diastolic pressures. The beneficial effects seem to be limited to the nondihydropyridines **verapamil** and **diltiazem** (Table 10.7). Conversely, dihydropyridine CCBs may be contraindicated (see below).
   b. Because of the unpredictable hemodynamic effects of their vasodilator properties, CCBs should be administered cautiously to patients with considerable outlet obstruction and elevated pulmonary pressures.
3. **Disopyramide**, a class 1a antiarrhythmic agent, may be an effective alternative or adjunct to β-blocker and CCB therapy. Its strong negative inotropic qualities coupled with its ability to suppress ventricular and supraventricular arrhythmias make it an effective treatment when marked outflow obstruction or arrhythmias are manifested. Potential disadvantages are anticholinergic properties, accumulation in patients with hepatic or renal dysfunction, the possibility of augmenting atrioventricular (AV) nodal conduction in the presence of atrial fibrillation, and

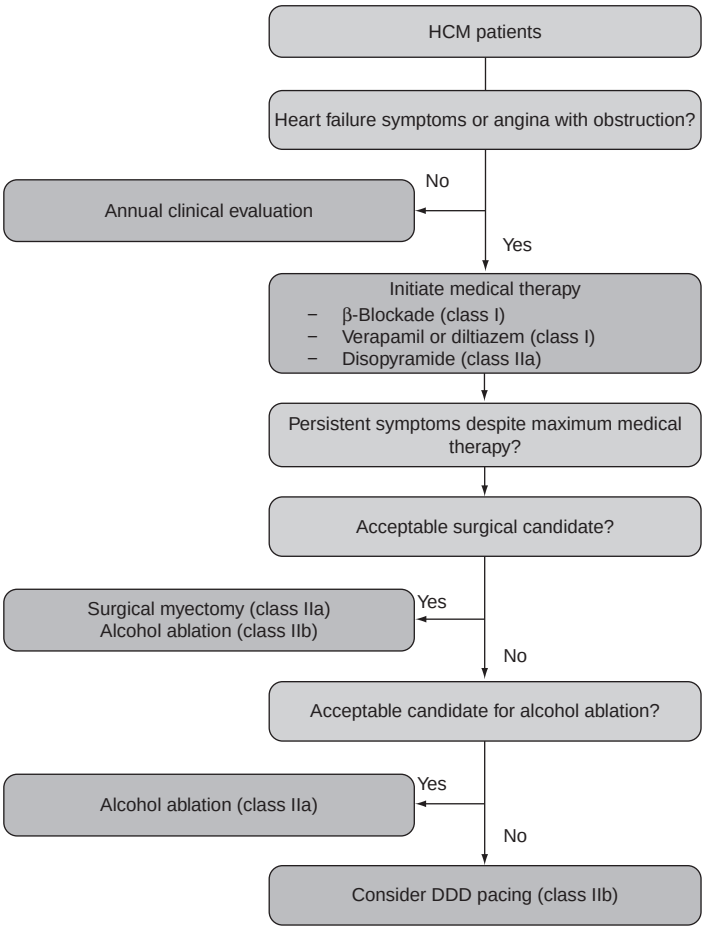

FIGURE 10.2 Management algorithm for hypertrophy cardiomyopathy. DDD, dual pacing for both chambers, dual chamber activity sensing, and dual response; HCM, hypertrophic cardiomyopathy. (Adapted from Gersh BJ, Maron BJ, Bonow RO, et al. 2011 ACC/AHA Guidelines for the Diagnosis and Treatment of Hypertrophic Cardiomyopathy. *Circulation* 2011;124:e783–e831)

waning hemodynamic effects with time. It is because of these significant side effects that disopyramide is typically used in a very symptomatic patient when a more definitive procedure is being planned, such as surgical myectomy or alcohol septal ablation. It is not considered to be a long-term treatment for HCM.

4. **Dihydropyridine CCBs** (e.g., nifedipine and amlodipine), **angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers** should be avoided because they cause peripheral vasodilation, which may result in decreased LV filling and worsening of outflow tract obstruction.

TABLE 10.7 Pharmacologic Therapy for Hypertrophic Cardiomyopathy

Drug	Standard dose[a] (mg/d)
β-Blockers	
Metoprolol	50–200
Atenolol	50–100
Calcium channel antagonists	
Verapamil	120–360
Diltiazem	120–360
Antiarrhythmics	
Disopyramide	400–1,200
Amiodarone	200–400
Sotalol	160–320

[a]Doses can be increased to treat patients with persistent symptoms who have no evidence of an adverse response.

5. **Diuretics** should be used cautiously as high filling pressures are often necessary due to the stiff ventricle, and overdiuresis may reduce LV size and increase obstruction.
6. **Digoxin** should be avoided due to potential worsening of the LVOT obstruction secondary to the positive inotropic effect.
7. **Phenylephrine**, a pure α-agonist that causes vasoconstriction, can be considered in cases of refractory hypotension unresponsive to IV fluids. Pressors with positive inotropic effects, such as norepinephrine, dopamine, and dobutamine, can provoke LVOT obstruction and should be avoided.

C. **Nonpharmacologic treatment** is typically reserved for those patients with symptoms despite optimal medical therapy (Table 10.8). With severe symptomatic, nonobstructive HCM, cardiac transplantation remains the only option. However, persons with symptomatic obstruction and resting or latent gradient of 50 mm Hg or more despite optimal medical treatment are candidates for septal myectomy or alcohol septal ablation. Younger patients with gradients > 75 mm Hg and low surgical risk should be considered for septal myectomy even in the absence of symptoms.

1. **Septal myectomy** of HCM has been performed for more than 50 years and is the **procedure of choice for patients with progressive, drug-refractory functional limitation due to LVOT obstruction.**
   a. When performed by an experienced surgeon, septal myectomy is considered the most definitive treatment and is associated with a mortality rate of < 1% to 2%. It is effective in abolishing resting gradients in > 90% of patients, and most patients have long-lasting symptomatic relief. Enlargement of the LVOT has been found to reduce SAM, MR, LV systolic and end-diastolic pressures, left atrial pressure, and resting gradients. A retrospective study by Ommen et al. (1) from the Mayo Clinic published in 2005 demonstrated that patients who underwent myectomy had significantly longer survival and less incidence of SCD as compared with patients with obstruction who did not undergo surgery. In fact, after myectomy, survival was no different as compared with HCM patients who did not have obstruction at baseline.

TABLE 10.8 Excerpts from 2011 ACC/AHA Guidelines for the Diagnosis and Treatment of Hypertrophic Cardiomyopathy

Invasive therapies—recommendations

Class I

Septal reduction therapy should be performed only by experienced operators in the context of a comprehensive HCM clinical program and only for the treatment of eligible patients with severe drug-refractory symptoms and LVOT obstruction.

Class IIa

Consultation with centers experienced in performing both surgical septal myectomy and alcohol septal ablation is reasonable when discussing treatment options for eligible patients with HCM with severe drug-refractory symptoms and LVOT obstruction. *(Level of Evidence: C)*

Surgical septal myectomy, when performed in experienced centers, can be beneficial and is the first consideration for the majority of eligible patients with HCM with severe drug-refractory symptoms and LVOT obstruction. *(Level of Evidence: B)*

Surgical septal myectomy, when performed at experienced centers, can be beneficial in symptomatic children with HCM and severe resting obstruction (> 50 mm Hg) for whom standard medical therapy has failed. *(Level of Evidence: C)*

When surgery is contraindicated or the risk is considered unacceptable because of serious comorbidities or advanced age, alcohol septal ablation, when performed in experienced centers, can be beneficial in eligible adult patients with HCM with LVOT obstruction and severe drug-refractory symptoms (usually NYHA functional class III or IV). *(Level of Evidence: B)*

Class IIb

Alcohol septal ablation, when performed in experienced centers, may be considered as an alternative to surgical myectomy for eligible adult patients with HCM with severe drug-refractory symptoms and LVOT obstruction when, after a balanced and thorough discussion, the patient expresses a preference for septal ablation. *(Level of Evidence: B)*

The effectiveness of alcohol septal ablation is uncertain in patients with HCM with marked (i.e., > 30 mm) septal hypertrophy, and therefore the procedure is generally discouraged in such patients. *(Level of Evidence: C)*

Selection of patients for ICD

Class I

The decision to place an ICD in patients with HCM should include application of individual clinical judgment, as well as a thorough discussion of the strength of evidence, benefits, and risks to allow the informed patient's active participation in decision making. *(Level of Evidence: C)*

ICD placement is recommended for patients with HCM with prior documented cardiac arrest, ventricular fibrillation, or hemodynamically significant VT. *(Level of Evidence: C)*

Class IIa

It is reasonable to recommend an ICD for patients with HCM with

1. Sudden death presumably caused by HCM in one or more first-degree relatives. *(Level of Evidence: C)*
2. A maximum LV wall thickness ≥ 30 mm. *(Level of Evidence: C)*
3. One or more recent, unexplained syncopal episodes. *(Level of Evidence: C)*

(Continued)

TABLE 10.8 Excerpts from 2011 ACC/AHA Guidelines for the Diagnosis and Treatment of Hypertrophic Cardiomyopathy (*Continued*)

An ICD can be useful in select patients with NSVT (particularly those < 30 years of age) in the presence of other SCD risk factors or modifiers. *(Level of Evidence: C)*

An ICD can be useful in select patients with HCM with an abnormal blood pressure response with exercise in the presence of other SCD risk factors or modifiers. *(Level of Evidence: C)*

It is reasonable to recommend an ICD for high-risk children with HCM, based on unexplained syncope, massive LV hypertrophy, or family history of SCD, after taking into account the relatively high complication rate of long-term ICD implantation. *(Level of Evidence: C)*

Class IIb

The usefulness of an ICD is uncertain in patients with HCM with isolated bursts of NSVT in the absence of any other SCD risk factors or modifiers. *(Level of Evidence: C)*

The usefulness of an ICD is uncertain in patients with HCM with an abnormal blood pressure response with exercise when in the absence of any other SCD risk factors or modifiers, particularly in the presence of significant outflow obstruction. *(Level of Evidence: C)*

Participation in competitive or recreational sports and physical activity

Class IIa

It is reasonable for patients with HCM to participate in low-intensity competitive sports (e.g., golf and bowling). *(Level of Evidence: C)*

Management of AF

Class I

Anticoagulation with vitamin K antagonists (i.e., warfarin, to an INR of 2.0 to 3.0) is indicated in patients with paroxysmal, persistent, or chronic AF and HCM. *(Level of Evidence: C)*

Ventricular rate control in patients with HCM with AF is indicated for rapid ventricular rates and can require high doses of β-antagonists and nondihydropyridine calcium channel blockers. *(Level of Evidence: C)*

Class IIa

Disopyramide (with ventricular rate-controlling agents) and amiodarone are reasonable antiarrhythmic agents for AF in patients with HCM. *(Level of Evidence: C)*

Radiofrequency ablation for AF can be beneficial in patients with HCM who have refractory symptoms or who are unable to take antiarrhythmic drugs. *(Level of Evidence: B)*

Maze procedure with closure of LA appendage is reasonable in patients with HCM with a history of AF, either during septal myectomy or as an isolated procedure in selected patients. *(Level of Evidence: C)*

Class IIb

Sotalol, dofetilide, and dronedarone might be considered alternative antiarrhythmic agents in patients with HCM, especially in those with an ICD, but clinical experience is limited. *(Level of Evidence: C)*

AF, atrial fibrillation; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter–defibrillator; INR, international normalized ratio; LA, left atrial; LV, left ventricular; LVOT, left ventricular outflow tract ; NSVT, nonsustained ventricular tachycardia; SCD, sudden cardiac death; VT, ventricular tachycardia. From Gersh BJ, Maron BJ, Bonow RO, et al. 2011 ACCF/AHA Guideline for the Diagnosis and Treatment of Hypertrophic Cardiomyopathy. *Circulation* 2011;124:e783–e831.

2. **Alcohol septal ablation**—essentially a controlled infarction of the septum—is an alternative to septal myectomy. Because it has a greater risk than myectomy of complications including complete heart block and extensive myocardial infarction, it is **generally used in patients who are not candidates for surgical myectomy**. There are no randomized trials comparing myectomy and septal ablation.
   a. **Technique.** In the cardiac catheterization laboratory, a guidewire is advanced through the left main trunk to probe the first or second septal perforator, or both. An angioplasty catheter is placed in the proximal portion of the septal branch for vessel isolation. Ultrasonic contrast agents are infused in the cannulated perforator to define the area at risk for infarction. Infusion of 1 to 4 mL of absolute alcohol causes infarction in the zone of septal myocardium served by the cannulated septal branch. In most centers, a temporary ventricular pacing catheter is placed into the RV apex before performing the ablation, in order to manage any transient conduction abnormalities.
   b. **Results.** In the majority of patients, there is a marked immediate decrease in the LVOT gradient. This gradient response is thought to be triphasic: immediate reduction (due to stunning), early reappearance, and sustained fall by 3 months after the procedure (due to remodeling). Within this initial period, most patients attain good symptomatic relief. Risks of the procedure include high-grade AV block, coronary dissection, large anterior wall myocardial infarction, pericarditis, and electrical instability of the scar that forms as a result of the infarction. In a Scandinavian study by Jensen et al. of 313 alcohol septal ablation procedures performed in 279 patients, mortality was low at 0.6%, but 20% of patients required implantation of a pacemaker (2).
3. **Dual-chamber pacing** has been previously used in hopes of alleviating symptoms by altering the timing of septal contraction, but studies have not confirmed any long-term benefit. Dual-chamber pacing should only be considered in patients with medically refractory symptoms who are not candidates for septal reduction therapy.
4. **Special management considerations**
   a. **Atrial fibrillation**, which occurs in up to a third of patients with HCM, can have devastating consequences. Atrial fibrillation decreases diastolic filling time and causes the loss of atrial systole. These changes can lead to acute hemodynamic decompensation and pulmonary edema given the stiff left ventricle of patients with HCM. Because of the increased risk of thromboembolism, all patients with HCM-associated atrial fibrillation (be it paroxysmal or permanent) should be strongly considered for anticoagulation therapy. Aggressive efforts should be made to maintain sinus rhythm given the increased morbidity and mortality associated with atrial fibrillation in patients with HCM.
      (1) **Acute paroxysms** of atrial fibrillation are best managed with prompt cardioversion with transesophageal echocardiogram (TEE). Data concerning the prevention of recurrence are lacking, but the 2006 ACC/AHA Guidelines for the Management of Patients with Atrial Fibrillation suggest disopyramide or amiodarone as possible agents. Other class III agents, such as dofetilide, sotalol, and dronedarone, should be reserved for use in patients with an ICD given the paucity of safety data.
      (2) **Chronic atrial fibrillation** may be well tolerated if the heart rate is controlled with β-blockers or calcium channel antagonists.
      (3) **Maze or radiofrequency ablation.** For patients who do not tolerate atrial fibrillation and cannot be maintained in sinus rhythm, AV nodal ablation and implantation of a dual-chamber pacemaker may be an option. Other options including catheter ablation or combined surgical myectomy–maze can be considered.

b. Risk stratification for sudden death remains one of the more challenging aspects for the management of HCM, especially for primary prevention. Table 10.9 lists the established factors for risk stratification. Additional risk factors (e.g., scar burden as determined by late gadolinium contrast on MRI) continue to be evaluated. Currently, the only effective means of preventing SCD is an ICD.

(1) Placement of an ICD carries several potential complications, including but not limited to infection, inappropriate firing, lead fracture, and generator depletion. The **decision to implant an ICD is highly individualized** and should take into consideration that younger patients will be subject to a higher risk of device-related complications due to the longer time the device will be present.

(2) Patients who survive an episode that might have ended in sudden death, have sustained ventricular arrhythmias, or have multiple risk factors for sudden death should be strongly considered for an ICD.

(3) Selection of patients for ICD implantation as primary prevention is difficult. A retrospective multicenter study from the Minneapolis Heart Institute Foundation (3) evaluated the incidence of appropriate ICD interventions in patients with HCM who previously received a device for one of four SCD risk factors: history of HCM-related SCD in a relative younger than 50 years, "massive" LV hypertrophy, nonsustained ventricular tachycardia on Holter monitoring, and prior unexplained syncope (nonneurocardiogenic). The study concluded that one risk factor may be enough for consideration of ICD implantation. Of note, there was no control group in this study.

VII. SPECIAL CONSIDERATIONS

A. Athlete's heart

1. Differentiating HCM from hypertrophy of athletes. Failure to diagnose HCM places an athlete at undue risk for sudden death while incorrect labeling of HCM often leads to irrational treatments, unnecessary fears, and inappropriate recommendations concerning exercise. Diagnostic uncertainty is greatest when maximal diastolic LV wall thickness exceeds the upper limit of normal (12 mm) but is less than the defined lower limit of expected hypertrophy (15 mm) for HCM and in the absence of SAM and LV outflow obstruction.

a. Characteristics that **substantiate the diagnosis of HCM** include unusual patterns of hypertrophy, an LV end-diastolic diameter of < 45 mm, septal thickening > 15 mm, left atrial enlargement, abnormal diastolic function, family history of HCM, and abnormal LV filling.

TABLE 10.9 Risk Factors for Sudden Cardiac Death

Previous cardiac arrest
Sustained ventricular tachycardia
Prolonged or repetitive episodes of nonsustained ventricular tachycardia on Holter monitor
Left ventricular wall thickness > 30 mm
Family history of SCD
No change or a decrease in blood pressure with exercise
Syncope or near-syncope

SCD, sudden cardiac death.

b. Findings more consistent with the **hypertrophied heart of an athlete** are LV end-diastolic diameter > 45 mm, septal thickening < 15 mm, left atrial size < 4 cm, LV end-diastolic diameter > 45 mm, and a decrease in LV thickness with deconditioning.

Should differentiation not be possible, the patient should stop training: after several months, ventricular hypertrophy will typically regress in the athlete but will persist in a patient with HCM.

2. Participation in sports. HCM is the most common cause of sudden death in young athletes. It appears that intense exercise, with its resulting rapid changes in hemodynamics, can increase the risk of death as well. The European Society of Cardiology recommends prohibiting athletes with HCM from participating in competitive high school and college sports. These recommendations remain in force after medical or surgical intervention.

a. Athletes with HCM with or without obstruction who are younger than 30 years should **not** participate in competitive, aerobically demanding sports.

b. Participation in recreational sports should take into consideration the intensity of the activity (with the resulting fluctuations in hemodynamics) and the danger to the individual should impaired consciousness occur. For instance, activities such as rock climbing and weightlifting carry a higher risk of morbidity and mortality than activities such as golf and bowling.

B. Infective endocarditis (IE)

1. Predisposing factors. Gastrointestinal and genitourinary tract surgical procedures place patients at increased risk for bacteremia. It is unclear if dental procedures place patients with HCM at risk.

2. Pathophysiology. Bacterial seeding of endomyocardial lesions is caused by repeated trauma associated with hemodynamic and intrinsic valvular abnormalities.

3. Prophylaxis. Guidelines on the prevention of IE published by the AHA in 2007 question the practice of treating patients with HCM with antibiotics prior to dental procedures and recommend against it except in the setting of prior endocarditis. However, there are no large, prospective, randomized double-blind trials testing the efficacy of IE prophylaxis. Given the catastrophic consequences of endocarditis in patients with HCM, routine antimicrobial prophylaxis for IE should be weighed on an individual basis.

C. Yamaguchi's or Apical HCM

1. Clinical presentation. Patients experience chest pain, dyspnea, fatigue, and, in rare instances, sudden death.

2. Prevalence. Within Japan, apical HCM constitutes 25% of all cases of HCM. Outside Japan, only 1% to 2% of cases are associated with isolated apical hypertrophy.

3. Diagnostic testing

a. An **ECG** reveals giant negative T waves in the precordial leads and LV hypertrophy (Fig. 10.3).

b. Echocardiographic findings include the following:

(1) Localized hypertrophy in the distal left ventricle beyond the origin of the chordae tendineae

(2) Wall thickness in the apical region of at least 15 mm or a ratio of maximal apical to posterobasal thickness > 1.5

(3) Exclusion of hypertrophy in other parts of the ventricular wall

(4) No LVOT obstruction or gradient

c. MRI demonstrates localized hypertrophy to the cardiac apex. MRI is useful in the care of patients with poor echocardiographic windows.

d. Cardiac catheterization reveals a spadelike configuration of the LV cavity at end diastole and apical end-systolic LV cavity obliteration.

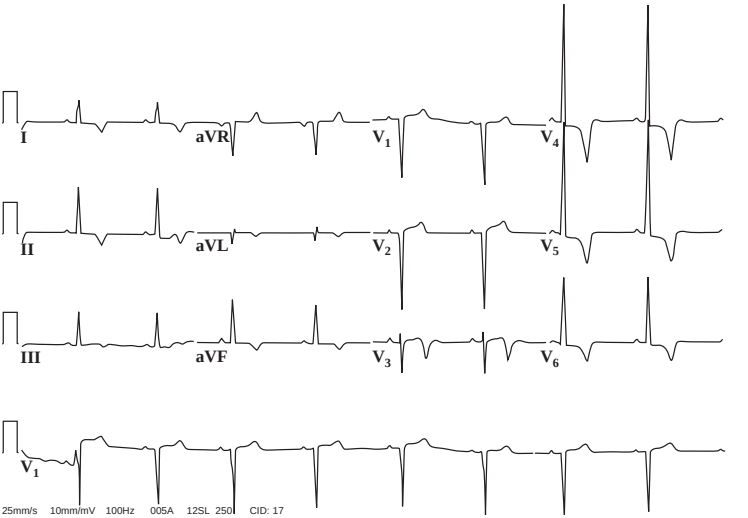

FIGURE 10.3 Electrocardiogram (ECG) in an apical hypertrophic cardiomyopathy (HCM, Yamaguchi). The classic ECG for apical HCM has deep anteroapical T-wave inversions.

4. **Prognosis** is favorable compared with that associated with other forms of HCM.
5. **Therapy.** Therapeutic efforts are limited to management of diastolic dysfunction with β-blockers and calcium channel antagonists.

D. HCM among the elderly

1. **Clinical presentation.** In addition to the signs and symptoms of other forms of HCM, hypertension is more common with HCM in the elderly population.
2. **Incidence.** Although the incidence is unknown, HCM among the elderly is probably more common than expected.
3. **Genetic aspects.** Reports have suggested that the delayed expression of mutations in the gene for cardiac myosin-binding protein C may play an important role in HCM in the elderly.
4. **Echocardiographic findings** for elderly patients (65 years or older) are compared with findings for young patients (40 years or younger) as follows:
   a. **Common findings**
      (1) LVOT gradient, both provocable and at rest
      (2) Asymmetric hypertrophy
      (3) SAM of the mitral valve
   b. **Differences pertaining to the elderly**
      (1) Less hypertrophy
      (2) Less RV involvement
      (3) Ovoid versus crescentic left ventricle
      (4) Prominent septal bulge (i.e., sigmoid septum)
      (5) More acute angle between the aorta and septum as the aorta uncoils with age
      (6) Management of HCM in the elderly is similar to that of other forms of HCM.
      (7) The **prognosis** is favorable compared with that for forms of HCM that occur at a younger age.

E. Screening of family members. With familial HCM, the dominant pattern of inheritance imparts a 50% chance of disease transmission to offspring.

- **a.** Serial 12-lead ECG and transthoracic echocardiogram are recommended **every 12 to 18 months in first-degree relatives** of HCM patients starting at age 12 during adolescence due to the propensity of HCM to worsen during growth spurts.
- **b.** Because of the possibility of late-onset phenotypic expression, **screening of first-degree relatives should continue into middle age**, but the frequency of screening can be scaled back to a minimum of every 5 years once full growth has been obtained.
- **c.** If genetic testing reveals a mutant HCM gene in the offspring, the high penetrance of the mutation imparts a > 95% lifetime risk of developing clinical and/or phenotypic evidence of disease. These gene-positive offspring should continue with serial examinations.
- **d.** First-degree relatives that are mutation negative have no risk of developing HCM and do not need further screening.

CHAPTER 11

Mosi K. Bennett
W.H. Wilson Tang

Myocarditis

I. INTRODUCTION. Myocarditis is defined as an inflammatory infiltration of the myocardium with associated necrosis or degeneration, or both. The disease is also known as **inflammatory cardiomyopathy** (or myocarditis with cardiac dysfunction in the World Health Organization 1995 classification for cardiomyopathy). The incidence and prevalence of myocarditis are unclear; the syndrome is underdiagnosed because of the large number of asymptomatic cases. Myocarditis usually affects younger individuals; the median age of patients with lymphocytic myocarditis is 42 years.

A. Clinicopathologic classification of myocarditis is clinically oriented but not widely used.

1. **Fulminant myocarditis** (17%) usually has a distinct onset. It can result in either complete, spontaneous resolution or rapidly progressive deterioration and death due to severe cardiac compromise. Usually there are multiple active foci of inflammatory infiltrate on histology with complete resolution.
2. **Acute myocarditis** (65% of myocarditis cases) has an indistinct onset, with moderate cardiovascular compromise and incomplete recovery, often resulting in cardiac dysfunction or subsequent death. Histologically, there are active or borderline inflammatory infiltrates that resolve completely over time.
3. **Chronic active myocarditis** (11% of myocarditis cases) has a presentation similar to that of acute myocarditis, but the chronic form usually progresses to only mild or moderate cardiac dysfunction, occasionally with restrictive physiology. Histologic examination often shows ongoing fibrosis, suggesting chronic inflammatory changes.
4. **Chronic persistent myocarditis** (7% of myocarditis cases) has an indistinct onset, with nonresolving active or borderline inflammatory infiltrates seen on histologic examination. Usually, there is no cardiovascular compromise.

B. Histologic classification of myocarditis, also called the Dallas classification (1986)

1. Initial biopsy
   - **a.** Myocarditis: myocardial necrosis or degeneration, or both, in the absence of significant coronary artery disease with adjacent inflammatory infiltrates or fibrosis, or both
   - **b.** Borderline myocarditis: inflammatory infiltrates too sparse or myocyte damage not apparent
   - **c.** No myocarditis: no inflammatory infiltrates or myocyte damage
2. Subsequent biopsy
   - **a.** Ongoing (persistent) myocarditis or fibrosis, or both
   - **b.** Resolving (healing) myocarditis or fibrosis, or both
   - **c.** Resolved (healed) myocarditis or fibrosis, or both

C. World Health Organization (Marburg Criteria, 1996). A minimum of 14 infiltrating leukocytes per mm (1), preferably T lymphocytes, and up to 4 macrophages may be included.

II. CLINICAL PRESENTATION

A. Signs and symptoms

1. Myocarditis can be **totally asymptomatic** or can manifest with **chest pain syndromes** ranging from mild persistent chest pain of acute myopericarditis (35% of cases) to severe symptoms that mimic acute myocardial infarction. Chest pain associated with coronary artery vasospasm may rarely occur in patients with myocarditis. Alternatively, chest pain may be more typical for pericarditis, suggesting pericardial involvement.
2. About 60% of patients may have antecedent arthralgias, malaise, fever, sweats, or chills consistent with viral infections (e.g., pharyngitis, tonsillitis, and upper respiratory tract infection) 1 to 2 weeks before onset.
3. The hallmark symptoms are those of **heart failure** (e.g., dyspnea, fatigue, and edema). In many patients who develop heart failure, fatigue and decreased exercise capacity are the initial manifestations. However, diffuse, severe myocarditis can progress rapidly and result in acute myocardial failure and cardiogenic shock. The diagnosis is usually presumptive, based on patient demographics and the clinical course (i.e., spontaneous recovery after supportive care).
4. In some instances, patients may present with **arrhythmia** in the form of syncope, palpitations caused by heart block (i.e., Stokes-Adams attack), ventricular tachyarrhythmia, or even sudden cardiac death. Sinus tachycardia is more frequent than serious atrial or ventricular arrhythmias. Palpitations secondary to premature atrial or ventricular extrasystoles are common.

B. Physical findings. Patients often present with signs of **acute decompensated heart failure**, including an S_3 (third heart sound) gallop, central and peripheral edema, jugular venous distention, and tachycardia (see Chapter 8). An audible pericardial friction rub may accompany concomitant myopericarditis. Specific findings in special cases are as follows:

1. **Sarcoid myocarditis:** lymphadenopathy, also with arrhythmias, and sarcoid involvement in other organs (up to 70%)
2. **Acute rheumatic fever** (usually affects heart in 50% to 90%)**:** associated signs such as erythema marginatum, polyarthralgia, chorea, and subcutaneous nodules **(i.e., Jones criteria)**
3. **Hypersensitive or eosinophilic myocarditis:** pruritic maculopapular rash and history of onset temporally related to initiation of potential culprit medications
4. **Giant cell myocarditis (GCM):** sustained ventricular tachycardia in rapidly progressive heart failure
5. **Peripartum cardiomyopathy:** heart failure developing in the last month of pregnancy or within 5 months after delivery (see Chapter 38)

III. LABORATORY EVALUATION

A. Inflammatory markers of myocarditis

1. **Complete blood count.** Leukocytosis is common (often lymphocytic), although the presence of eosinophilia may suggest hypersensitive (eosinophilic) myocarditis.
2. **Elevated acute phase reactants** such as erythrocyte sedimentation rates or ultrasensitive C-reactive protein are good monitors of clinical progression or response to therapy, but they have **low specificity** for myocarditis. Novel inflammatory markers under investigation include tumor necrosis factor-α, interleukins, interferon-γ, serum-soluble Fas, and soluble Fas ligand levels. Elevation of these markers portends a worse prognosis.
3. **Serum viral antibody titers** are usually increased fourfold or more acutely and gradually fall during convalescence. However, measurement of viral antibody titers is rarely indicated.
4. **Anticardiac antibody titers.** Because of their low specificity, measurement of anticardiac antibody titers (against sarcolemma, myosin, laminin, ADP/ATP

translocator, or β-adrenergic receptors) is not indicated (only 62% of myocarditis cases have titers ≥1:40).

B. Rheumatologic screening. Screening of antinuclear antibodies and rheumatoid factor is often indicated. Disease-specific testing is indicated if the following conditions are suspected:

1. Systemic lupus erythematosus: anti-dsDNA (reported positive anti-Ro/SSA and anti-La/SSB in lupus carditis in children)
2. Polymyositis: anti-Jo_1
3. Wegener's granulomatosis: c-ANCA (antineutrophil cytoplasmic antibody)
4. Scleroderma: anti-Scl_{70}

C. Serum cardiac enzymes (markers of myonecrosis)**:** creatinine kinase (myoglobin subfraction) is elevated in only 7.5% of patients with biopsy-proven myocarditis, whereas the cardiac **troponin I or T is elevated in at least 50% of patients** with biopsy-proven myocarditis (89% to 94% specificity and 34% to 53% sensitivity).

IV. DIAGNOSTIC TESTING

A. Electrocardiogram. The electrocardiogram often reveals sinus tachycardia, although the presence of nonspecific ST-segment and T-wave abnormalities may represent focal or global ischemia. Occasionally, the changes in electrocardiogram are suggestive of an acute myocardial infarction and may include ST-segment elevation. Pericarditis can accompany myocarditis and is often manifested in pericarditislike changes seen in electrocardiography. The sensitivity of the electrocardiogram for myocarditis is low (47%). In some cases, fascicular block or atrioventricular conduction disturbances and ventricular tachyarrhythmia may be hemodynamically significant.

B. Echocardiogram. A complete echocardiogram is standard procedure for patients with suspected myocarditis to exclude alternative causes of heart failure, detect the presence of intracardiac thrombi and associated valvular disease, and quantify the degree of left ventricular (LV) dysfunction to monitor response to therapy.

1. Occasionally, focal wall motion abnormalities and presence of pericardial fluid may prompt further workup or intervention.
2. Fulminant myocarditis is often characterized by near-normal diastolic dimensions and increased septal wall thickness, whereas acute myocarditis often has increased diastolic dimensions but normal septal wall thickness.
3. In a series of 23 patients with biopsy-proven myocarditis, significant reduction in right ventricular function was a powerful predictor of death or the need for cardiac transplantation.

C. Other imaging modalities

1. **Antimyosin scintigraphy (indium III monoclonal antimyosin antibody)** provides identification of myocardial inflammation, with a high sensitivity (91% to 100%) and negative predictive value (93% to 100%) but low specificity (28% to 33%).
2. **Gallium scanning** identifies severe myocardial cellular infiltration with high specificity (98%) but low sensitivity (36%).
3. **Gadolinium-enhanced magnetic resonance imaging (MRI)** is being used more frequently for diagnosis based on several small observational studies that have found up to 100% sensitivity and specificity depending on the protocol. In one study, MRI was also used for guiding biopsy to areas of focal increased uptake of gadolinium in patients with clinically suspected myocarditis with significantly higher diagnostic yield compared with those who did not have enhancing areas with which to guide the bioptome.

D. Coronary angiography. Cardiac angiography is often indicated to rule out coronary artery disease as the cause of new-onset heart failure, as the clinical presentation of myocarditis may mimic myocardial infarction (i.e., pseudoinfarct pattern), especially if there are focal wall motion abnormalities and localizing electrocardiographic changes.

V. ETIOLOGY. Up to 50% of all cases may not have a clear underlying cause (i.e., idiopathic cases).

A. Infective causes (Table 11.1)

1. Viral myocarditis. Cardiotropic viruses such as enteroviruses (specifically the coxsackie group B and echoviruses) may cause direct cardiotoxic injuries, cytokine activation, cytoskeletal damage, and autoimmune responses. However, data suggest that the incidence of myocarditis after infection is lower than previously projected. Viral myocarditis is often considered when accompanied with a clinical

TABLE 11.1 Causes of Myocarditis

Cause	Examples
Infectious causes	
Viruses	Enteroviruses, coxsackievirus A and B, echovirus, influenza virus, poliovirus, herpesviruses, adenovirus, mumps, rubella, rubeola, hepatitis B or C virus, human immunodeficiency virus, Epstein-Barr virus, cytomegalovirus, and parvovirus B19
Rickettsia	Rocky Mountain spotted fever
Fungi	Cryptococcosis, aspergillosis, coccidioidomycosis, and histoplasmosis
Protozoa	*Trypanosoma cruzi* (Chagas disease) and *Toxoplasmosis gondii*
Helminths	Trichinosis and schistosomiasis
Bacteria	*Legionella*, *Clostridium*, streptococci, staphylococci, *Salmonella*, and *Shigella*
Spirochetes	*Borrelia burgdorferi* (Lyme disease)
Noninfectious causes	
Hypersensitive reaction	Eosinophilic myocarditis
Cardiotoxic drugs	Catecholamines, amphetamines, cocaine, chemotherapeutic drugs (e.g., anthracyclines, fluorouracil, streptomycin, cyclophosphamide, interleukin-2, trastuzumab [Herceptin]), and small pox vaccine
Collagen vascular diseases	Systemic lupus erythematosus (i.e., lupus carditis), Wegener's granulomatosis or Churg-Strauss syndrome, dermatomyositis or polymyositis, and scleroderma
Systemic illnesses	Sarcoidosis, giant cell myocarditis, Kawasaki disease, large-vessel vasculitis (e.g., polyarteritis nodosa and Takayasu arteritis), and inflammatory bowel diseases (e.g., ulcerative colitis and Crohn disease)
Acute rheumatic fever	
Bites and stings	Venoms of scorpions, snakes, wasps, and black widow spiders
Chemicals	Hydrocarbons, carbon monoxide, thallium, lead, arsenic, and cobalt
Physical injury	Irradiation, heatstroke, and hypothermia
Childbirth	Peripartum cardiomyopathy
Alloantigens	Posttransplantation cellular rejection

picture of recent febrile illness, often with prominent myalgias, followed by rapid onset of cardiac symptoms. However, direct proof is lacking (and often unnecessary), and many cases of idiopathic dilated cardiomyopathies have been attributed to antecedent viral myocarditis. Antiviral therapies have not proved to be useful.

2. **Chagas disease.** Cardiomyopathy caused by *Trypanosoma cruzi* in South and Central America, particularly in persons aged 30 to 50 years. It is estimated that 16 to 18 million persons are infected with *T. cruzi* in Latin America. Cardiac involvement usually appears decades after initial treatment and is the leading cause of death of persons aged 30 to 50 years in the endemic areas.
   a. **Diagnosis**
      (1) Serologic test results should be positive for at least two types of tests (i.e., indirect immunofluorescence, indirect hemagglutination, complement fixation, immunoenzymatic, and radioimmune assays).
      (2) Cardiac lesions diagnosed by in situ polymerase chain reaction methods of analyzing biopsies.
      (3) Typical electrocardiographic changes include right bundle branch block with left anterior hemiblock, premature ventricular complexes, T-wave inversions, abnormal Q waves, variable atrioventricular blocks, low QRS voltage, and sick sinus syndrome.
      (4) Echocardiographic findings include LV aneurysm with or without thrombi, posterior basal akinesis or hypokinesis with preserved septal contraction, and diastolic dysfunction.
   b. **Clinical presentation**
      (1) The acute and subacute phases (i.e., 4 to 8 weeks of acute inflammation) consist for the most part of local inflammation at the parasite entry site and flulike symptoms. Occasionally hepatosplenomegaly and lymphadenopathy occur, but concomitant meningoencephalitis is rare. These manifestations often result from pathogen-induced cytotoxicity and inflammatory responses. More than 90% of cases resolve in 4 to 8 weeks without therapy.
      (2) The chronic phase (up to 10 to 30 years after acute infection) manifests with symptoms of palpitations, syncope, chest pain, and, subsequently, heart failure. Approximately 5% to 10% of affected patients may develop direct acute-to-chronic progression.
         (a) Heart failure (predominantly right sided in advanced stages) may develop in 25% to 30% of those affected.
         (b) Cerebral or pulmonary thromboembolism may occur in 10% to 15% of those affected.
         (c) Concomitant megaesophagus or megacolon may develop.
         (d) Apical LV aneurysm and apical fibrosis may develop.
      (3) Chagas disease is highly arrhythmogenic.
         (a) Frequent, complex ectopic beats and ventricular tachyarrhythmia occur in 40% to 90% of affected patients, with sudden cardiac death occurring in 55% to 65%.
         (b) Bundle branch block occurs in 50% of affected patients, and bradyarrhythmia with high-grade atrioventricular block occurs in 7% to 8%.
         (c) Atrial fibrillation develops in 7% to 10% of affected patients.
   c. Antibiotic therapy aims to reduce parasitemia and prevent complications.
      (1) Benznidazole (5 to 10 mg/kg/d q12h for 60 days) or
      (2) Nifurtimox (8 to 10 mg/kg po q24h for 90 to 120 days)
3. **Human immunodeficiency virus (HIV)–related cardiomyopathy.** HIV disease has been recognized as an important cause of dilated cardiomyopathy, with an estimated incidence of 1.6%. HIV type 1 (HIV-1) virions appear to infect myocardial cells in patchy distributions, leading to cytokine activation and progressive tissue damage. Cardiac autoimmunity, nutritional deficiencies, and drug

toxicities (i.e., mitochondrial damage from zidovudine and vasculitis or coronary artery disease associated with highly active antiretroviral therapy regimens) are possible contributing causes. In addition, other known viral pathogens, including cytomegalovirus, Epstein-Barr virus, and coxsackievirus B, have been isolated from endomyocardial biopsy (EMB) specimens of HIV-positive patients with myocarditis in conjunction with HIV nucleic acid sequences, suggesting that opportunistic viral infections may play an important role in the pathogenesis of this type of cardiomyopathy.

B. Peripartum cardiomyopathy (see Chapter 38)

C. Giant cell myocarditis (i.e., pernicious myocarditis, Fiedler's myocarditis, granulomatous myocarditis, or idiopathic interstitial myocarditis): This is a rare disorder with an unclear origin. The **hallmark feature is the presence of fused, multinucleated (> 20 nuclei) epithelioid giant cells of histocytic origin within a diffuse, intramyocardial inflammatory infiltrate with lymphocytes**.

1. GCM often presents with an **aggressive clinical course**, with progression over days to weeks. Rapidly progressive heart failure is the presentation in 75% of affected patients. Sustained ventricular tachyarrhythmia occurs in 29% of patients with GCM and atrioventricular block occurs in 50%.
2. The prognosis is **dismal without therapy**, but the disease is often refractory to standard medical therapy, with a 1-year mortality rate of up to 80% (median survival of 3 to 5 months from symptom onset).
3. Small observational series have suggested potential benefits of immunosuppressive therapy, and a randomized, prospective multicenter study is ongoing. Consideration for **early cardiac transplantation** is appropriate (71% 5-year survival after successful transplantation). Often, mechanical support may be required as a temporary bridge to recovery or transplantation. A 20% to 25% rate of histologic recurrence in surveillance EMBs has been observed after transplantation.

D. Hypersensitive reaction (i.e., eosinophilic myocarditis). Eosinophilic endomyocardial disease (i.e., Loeffler's endomyocardial fibrosis, see Chapter 9) occurs as a major complication of idiopathic hypereosinophilic syndrome as a result of direct toxic damage caused by eosinophil granule proteins within the heart. Drug-induced eosinophilic myocarditis is independent of cumulative dose and duration of therapy.

The absence of peripheral eosinophilia does not rule out eosinophilic myocarditis. Although observational series suggest potential clinical benefits of corticosteroid therapy, the best strategy is to remove the causative agent when known.

1. Medications that may cause eosinophilic myocarditis include the following:
   a. Antibiotics (e.g., ampicillin, chloramphenicol, tetracycline, and sulfisoxazole)
   b. Diuretics (e.g., hydrochlorothiazide and spironolactone)
   c. Anticonvulsants (e.g., phenytoin and carbamazepine)
   d. Other drugs (e.g., lithium, clozapine, and indomethacin)
   e. Tetanus toxoid
2. Collagen vascular diseases such as Wegener's granulomatosis or Churg-Strauss syndrome (i.e., allergic granulomatosis and vasculitis) may also lead to eosinophilic myocarditis.
3. Other causes include parasitic infection, drug hypersensitivity, and cellular rejection after cardiac transplantation, as well as postvaccinia myocarditis after small pox vaccination.

E. Systemic autoimmune disorders with myocarditis. Although the histologic appearance of myocarditis occurring as part of sarcoidosis, systemic lupus erythematosus, or polymyositis is similar to that seen in isolated myocarditis, the natural history is different. **Systemic causes of myocarditis often respond poorly to medical therapy and cardiac transplantation**, and their prognoses are often unfavorable. However, small retrospective surveys and case series have identified a significant decrease in mortality and improved clinical course among cardiac sarcoid patients treated with corticosteroids and other immunosuppression strategies.

VI. PROGNOSIS. On the basis of population studies, adults with myocarditis may present with few symptoms or with an acute toxic state of cardiogenic shock or frank heart failure (i.e., fulminant myocarditis). However, adults may present with heart failure years after the initial index event of myocarditis (up to 12.8% of patients with idiopathic dilated cardiomyopathy had presumed prior myocarditis in one case series).

A. Natural history and sequelae of myocarditis. The outlook is poor in the acute phase, regardless of clinicopathologic classification, but those surviving the acute phase have a more favorable prognosis (except for those with chronic active myocarditis).

1. Many patients may have **full spontaneous clinical recovery**, even after weeks of mechanical support (e.g., intra-aortic balloon counterpulsation and mechanical assist devices).
2. In the Myocarditis Treatment Trial, the 1-year mortality rate was 20% and the 4-year mortality rate was 56%.
3. In-hospital case series point to an 11-year survival rate of 93% for patients with fulminant myocarditis and 45% for nonfulminant myocarditis.
4. Evolution to dilated cardiomyopathy
   a. Up to one-half of patients with myocarditis develop subsequent cardiomyopathy over a range of 3 months to 13 years.
   b. Histologic evidence of myocarditis is seen in 4% to 10% of EMBs of patients with idiopathic dilated cardiomyopathy.
5. Severe heart block requiring permanent pacemaker placement occurs in 1% of patients.

B. Predictors for morbidity and mortality

1. Unfavorable factors for survival include extremes of **age** (i.e., very old or very young), **electrocardiographic abnormalities** (e.g., QRS alterations, atrial fibrillation, and low voltages), **syncope**, and **specific diagnoses** (e.g., peripartum cardiomyopathy and GCM).
2. Favorable factors for survival include normal ventricular function, shorter clinical history, and fulminant presentation at onset.

VII. TREATMENT

A. Heart failure management

1. Patients who present with myocarditis with acute dilated cardiomyopathy should be treated according to the current American Heart Association, the American College of Cardiology, the European Society of Cardiology, and the Heart Failure Society of America (HFSA) guidelines. Standard heart failure therapy consists of diuretics, angiotensin-converting enzyme inhibitors, β-blockers, and aldosterone antagonists. Studies have not been done to determine when and how to discontinue standard heart failure therapy in patients who recover LV function.
2. Because of its proarrhythmic properties in animal models, digoxin should be avoided.
3. Anticoagulation to prevent thromboembolic events is usually recommended in patients with apical aneurysm with thrombus (e.g., Chagas disease, atrial fibrillation, and prior embolic episodes).
4. Inotropic therapy is reserved for severe hemodynamic compromise, particularly in fulminant myocarditis.
5. Aggressive support with mechanical and surgical intervention is often indicated (see Chapters 8 and 12).
   a. Intra-aortic balloon counterpulsation for hemodynamic support and afterload reduction
   b. Mechanical assistive devices (left ventricular assist device)
   c. Extracorporeal membrane oxygenation

6. Early consideration for cardiac transplantation should be given, especially for patients with progressive, biopsy-proven GCM or peripartum cardiomyopathy. However, patients with myocarditis have increased rates of rejection and reduced survival after heart transplantation compared with those without myocarditis, and recurrent disease may affect the allograft.

B. Exercise restriction

1. There is a theoretical increased risk of myocardial inflammation and necrosis, cardiac remodeling, and death, as shown in animal models.
2. Patients are usually advised to abstain from vigorous exercise for up to 6 months or longer after the onset of symptoms. The length of activity restriction can be based on recovery of LV function.

C. Arrhythmia management

1. Antiarrhythmics provide the first-line treatment using standard therapy such as β-blockers, amiodarone, and sotalol.
2. Implantable cardioverter–defibrillators are used for patients stabilized in the chronic phase with persistently low ejection fraction (EF) and for those with malignant arryhythmias that are refractory to medical therapy.
3. Permanent pacemakers are used for heart block or bradyarrhythmia.

D. Follow-up

1. Clinical follow-up should be close because persistent chronic inflammation may lead to dilated cardiomyopathy. Initially, 1- to 3-month intervals are used for drug and physical activity titration.
2. Serial echocardiographic assessment of ventricular structure and function is often performed, although there is no agreement regarding the frequency of echocardiographic assessment after myocarditis.

E. Immunosuppressive therapy is reserved for refractory disease or biopsy-proven GCM. No benefits have been established for antiviral regimens or nonsteroidal antiinflammatory agents (see Section **VIII.B**). The most recent HFSA guidelines do not recommend routine use of immunosuppressive therapy in patients with myocarditis. More work is needed to identify patient cohorts who will benefit from tailored antiviral and immunosuppressive therapy.

VIII. CONTROVERSIES IN MYOCARDITIS

A. Endomyocardial biopsy

1. **Routine EMB confirmation of myocarditis is unnecessary.**
   a. EMB can be considered in those patients with a **rapid deterioration in cardiac function** of unknown etiology who do not respond to standard medical therapy.
   b. Incidence of biopsy-proven myocarditis in recent-onset, unexplained heart failure can be as low as 8% to 10%. Concerns have emerged that this is caused by low sensitivity of the Dallas criteria, and several recent trials of immunosuppressive therapy have utilized supplemental pathologic criteria to assess myocarditis, including upregulation of human leukocyte antigen, presence of virus, and anticardiac antibodies.
   c. **False-negative rates are high** (50% even in four or five biopsies) because of the small number of lymphocytes and difficulties in distinguishing cell types, with wide interobserver variability.
2. However, EMB may be considered in patients with the following conditions in which a diagnostic biopsy may provide information on prognosis and/or therapeutic possibilities (see Table 11.2):
   a. Rapidly progressive heart failure symptoms despite conventional therapy or new-onset frequent ventricular tachyarrhythmia or conduction disturbances
   b. Suspected specific causes of myocarditis (e.g., GCM, eosinophilic myocarditis, cardiac sarcoidosis, and vaccinia myocarditis)

TABLE 11.2 Relevant ACC/AHA Recommendations for the Role of Endomyocardial Biopsy

Scenario	Class of recommendation
New-onset heart failure of < 2 wk duration associated with a normal-sized or dilated left ventricle and hemodynamic compromise	I
New-onset heart failure of 2 wk to 3 mo duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 wk	I
Heart failure of > 3 mo duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 wk	IIa
Heart failure associated with a dilated cardiomyopathy of any duration associated with suspected allergic reaction and/or eosinophilia	IIa
New-onset heart failure of 2 wk to 3 mo duration associated with a dilated left ventricle, without new ventricular arrhythmias, or second- or third-degree heart block that responds to usual care within 1–2 weeks	IIb
Heart failure of > 3 mo duration associated with a dilated left ventricle, without new ventricular arrhythmias, or second- or third-degree heart block that responds to usual care within 1–2 wk	IIb
Unexplained ventricular arrhythmias	IIb

Adapted from Cooper LT, Baughman KL, Feldman AM, et al. The role of endomyocardial biopsy in the management of cardiovascular disease. *Circulation 2007;* 116: 2216–2233.

3. Although specificity is high (98%), sensitivity has been found in some series to be as low as 10% to 22%. It increases with multiple biopsies, but postmortem examinations have found that more than 17 specimens were needed to make the diagnosis with 80% sensitivity in proven myocarditis cases.
4. **Biopsy** for staging of myocarditis:
   a. Cell types include lymphocytic, eosinophilic, neutrophilic, giant cell, granulomatous, and mixed.
   b. Amount of cells: none (grade 0), mild (grade 1), moderate (grade 2), and severe (grade 3).
   c. Distribution: focal (i.e., outside of vessel lumen), confluent, diffuse, and reparative (i.e., in fibrotic areas).
   5. Other tests:
   a. Immunohistochemical staining to examine upregulation of major histocompatibility complex antigens and quantify inflammation, although rates of correlation with biopsy-proven myocarditis have not been consistent between studies.
   b. Approximately 12% to 50% of patients with acute or chronic myocarditis have persistent viral mRNA detected in biopsy samples.

B. Immunosuppressive therapy in acute myocarditis

1. Routine immunosuppressive therapy is not recommended because of the neutral findings from multiple trials, including the Myocarditis Treatment Trial and the Intervention in Myocarditis and Acute Cardiomyopathy (IMAC) study. There is no Food and Drug Administration (FDA)–approved regimen for the treatment of acute or chronic myocarditis.

2. Considerations are reserved for patients with new-onset, rapidly deteriorating, advanced heart failure with suspicion of the following conditions:
   a. GCM is treated with combination therapy (Table 11.3).
   b. Eosinophilic or sarcoid myocarditis is treated with high-dose steroids.
   c. Specific therapy is used for underlying collagen vascular diseases, if present.

TABLE 11.3 Treatment Regimens for Myocarditis in Clinical Trials

Intervention in Myocarditis and Acute Cardiomyopathy (IMAC) study[a]

Intravenous immune globulin (Gamimune N, 10%): 1 g/kg/d IV × 2 d

Giant Cell Myocarditis study[b]

Cyclosporine: 25 mg po bid, increase by 25 mg increments to target level:

Monoclonal whole-blood immunoassay: 200–300 ng/mL

High-performance liquid chromatography assay: 150–250 ng/mL

Fluorescence polarization immunoassay serum-based polyclonal assay: 100–150 ng/mL

Dose reduction if renal dysfunction develops

Muromonab-CD3 (OKT-3): 5 mg IV qd × 10 d

Dose reduction if hypotension develops

Corticosteroid: methylprednisolone, 10 mg/kg IV qd × 3 d, followed by prednisone, 1–1.25 mg/kg with extended taper

Azathioprine: 200 mg po qd

Myocarditis Treatment Trial[c]

Corticosteroid/cyclosporine versus corticosteroid/azathioprine versus placebo (biopsy-proven myocarditis, LVEF < 45%, NYHA ≥ class II)

Oral prednisone: 1.25 mg/kg/d in divided doses × 1 wk; reduce oral dose by 0.08 mg/kg/wk until dose is 0.33 mg/kg/d at week 12; maintain oral dose until week 20 and then reduce dose by 0.08 mg/kg/wk until week 24; then off.

Oral cyclosporine: 5 mg/kg bid to achieve level of 200–300 ng/mL × 1 wk; adjust oral dose to achieve level of 100–200 ng/mL from weeks 2 to 4; adjust oral dose to achieve level of 60–150 ng/mL from weeks 4 to 24.

Immunosuppressive therapy for active lymphocytic myocarditis[d]

Prednisone 1 mg/kg/d for 4 wk; reduced to 0.33 mg/kg/d for 5 mo; azathioprine 2 mg/kg/d for 6 mo

LVEF, Left ventricular ejection fraction; NYHA, New York Heart Association.

3. Studies are ongoing in an attempt to identify markers to predict favorable response to immunosuppressive regimens. A study of 112 patients with histopathologic acute lymphocytic myocarditis who failed to improve with conventional therapy and subsequently received prednisone and azathioprine found that one-half of the treated group improved, with EF rising from 26% to 47% and improvement in biopsy findings. Of those who failed conventional therapy, those patients who responded to immunosuppression were significantly more likely to have positive cardiac antibodies (90% vs. 0%) and less likely to have viral persistence when compared with nonresponders (14% vs. 85%).

Nontransplantation Surgical Treatment for Chronic Heart Failure

I. INTRODUCTION. Even with optimal medical therapy, the morbidity and mortality associated with chronic heart failure (CHF) is significant. Fortunately, there are multiple possible surgical interventions available for these patients that may help to avoid or postpone the need for advanced salvage therapies and transplantation. Despite the improvement in surgical techniques and an enhanced understanding of the role of reconstructing structural abnormalities of the failing heart, safety and efficacy data are still limited for many of these procedures. Elective and planned procedures for advanced heart failure (e.g., revascularization, valvular surgery, left ventricular [LV] reconstructive surgery, and cardiomyoplasty) and urgent or bridging procedures (e.g., circulatory support devices and total artificial heart [TAH]) are discussed in this chapter. Surgical approaches to the management of heart failure must be accompanied by continued aggressive pharmacologic therapy.

II. SURGICAL REVASCULARIZATION FOR ISCHEMIC CARDIOMYOPATHY

A. Pathophysiology

1. Loss of coronary flow reserve in severe coronary artery disease leads to reduction in myocardial perfusion, tissue hypoxia, and myocardial dysfunction.
2. Myocardial infarction results in necrosis, scarring, and loss of contractile function. Sites distal to infarction undergo increased mechanical stress and adverse remodeling over time. Progressive ventricular dilation and impairment of systolic and diastolic function occur.
3. Chronic ischemia can decrease perfusion, leading to hibernation, repeated episodes of stunning, and recurrent infarction. The cardiomyocytes may shift metabolic states to hibernation. Thus, revascularization may help retain viability and recover function. Stunning and hibernation may be detected by various imaging modalities (see Chapter 50).
   a. **Stunning** is the loss of contractile function caused by a momentary total occlusion of blood flow with subsequent restoration of flow.
   b. **Hibernation** is the downregulation of myocardial function to match the chronic reduced blood flow. Hibernating cardiomyocytes manifest sustained glucose extraction, decreased glycogen content, and decreased contractile proteins and function.

B. Clinical significance

1. Heart failure, rather than angina or an acute coronary syndrome, is a common presentation of myocardial ischemia in patients with underlying cardiac dysfunction.
2. At least two-thirds of patients with cardiac dysfunction have evidence of epicardial coronary artery disease as the primary etiology. Coronary angiography is indicated when the suspicion of an ischemic cause for cardiomyopathy is high.

3. Some patients may have epicardial coronary artery disease superimposed on an underlying dilated cardiomyopathy. In this scenario, the presence of epicardial coronary artery disease may not necessarily explain the "degree" of depressed myocardial contractility. The role of revascularization remains unclear for these patients.

C. Recommendations

1. Most recently, the Surgical Treatment for Ischemic Heart Failure (STICH) trial reported that in patients with coronary artery disease amenable to coronary artery bypass grafting (CABG) and left ventricular ejection fraction (LVEF) < 35%, there was no difference in the trial's primary end point of all-cause mortality when treated with optimal medical therapy versus CABG. However, benefit was seen in the CABG group with respect to the secondary end point of cardiovascular death at follow-up. There were several limitations to this study: 30-day mortality was high in the CABG group and significant crossover occurred, both of which may have diminished the benefits of CABG in the primary intention to treat analysis.
2. Primary CABG should still be considered for patients with an LVEF > 15%, LV end-diastolic dimensions < 65 mm, distal vessels suitable for grafting, and evidence of a significant amount of ischemic or hibernating myocardium. These guidelines are arbitrary and many centers consider patients with more severe diseases.
3. Patients with hibernating myocardium and severe LV dysfunction who undergo CABG may achieve survival advantage comparable to those receiving cardiac transplantation (about 80% survival in 3 years).
   a. The potential for significant improvement in LV function and symptoms is assumed to be great enough to recommend revascularization when there are four or more viable segments of myocardium, representing approximately 31% of the left ventricle.
   b. Surgical revascularization of the patient with severe heart failure should generally be considered as part of a multifaceted approach, including evaluation for valve repair, ventricular reconstructive surgery, cryoablation for ventricular arrhythmias, and maze procedure or pulmonary vein isolation procedures for atrial dysrhythmias. To maximize the therapeutic benefit from this approach, aggressive complementary pharmacologic approaches are indicated postoperatively.

III. MITRAL VALVE SURGERY

A. Pathophysiology

1. As the ventricle fails, progressive dilation leads to abnormal geometry of the left ventricle, giving rise to mitral regurgitation (MR). MR results in progressive increase in volume overload of the left ventricle, progressive LV dilation, and further worsening of MR.
2. Other alterations of the annular–ventricular apparatus and ventricular geometry contribute to the pathogenesis of MR: papillary muscle ischemia or infarction, myocardial thinning and dilation, blunting of the aortomitral angle, widening of the interpapillary distance, and increased leaflet tethering leading to loss of the zone of coaptation.

B. Clinical significance and recommendations

1. Restoration of zone of coaptation by inserting an "undersized" annuloplasty ring may correct the MR and improve the LV geometry and cardiac output. However, mitral valve repair in ischemic cardiomyopathy ("ischemic MR") is less successful than in degenerative MR.
2. Subvalvular apparatus should be kept intact when possible.

3. In some patients, mitral valve surgery results in improved symptoms and measures of LV function and remodeling but not necessarily in improved survival.
4. In some patients, mitral valve repair with a figure-of-eight stitch (i.e., Alfieri approach) or the "edge-to-edge" technique may be used in addition to annuloplasty to secure the repair.
5. Mitral valve replacement is required in a minority of patients and may be associated with a significantly worse outcome.

IV. LV RECONSTRUCTIVE PROCEDURES

A. Pathophysiology

1. Laplace's law dictates that as the failing heart dilates, the intracavity radius increases and thus wall stress increases. The result is increased myocardial oxygen consumption and stimulation of adverse remodeling.
2. Surgical remodeling helps to decrease ventricular size and wall stress. Endoventricular circular patch plasty (EVCPP, also called the Dor procedure) is performed in patients with ischemic cardiomyopathy and significant areas of LV akinesis or dyskinesis. Partial LV resection, also called the Batista procedure, was performed in the past on patients with dilated, nonischemic cardiomyopathy. This was abandoned because of poor intermediate results and increased mortality, despite promising short-term outcomes.

B. Endoventricular circular patch plasty

1. Acute myocardial infarction leads to tissue necrosis, scar formation, followed by LV remodeling, leading to dilation and heart failure. The Dor procedure is suitable for patients with a left anterior descending artery territory scar or aneurysm with relatively preserved lateral and posterior LV wall function.
   a. It involves opening of the akinetic or dyskinetic scar and placement of a purse-string suture at the neck of the aneurysm. The residual opening may be closed with a Dacron patch, after which the ventriculotomy is closed by running sutures.
   b. This procedure is accompanied by CABG in >90% of cases. Additional valve and ablative surgical procedures are commonly performed.
2. Good candidates for EVCPP include patients with LV aneurysm (or large akinetic area), an increased LV end-systolic index, absence of scar in the circumflex territory, as well as good target tissue and viability for concomitant CABG. Assessment of the severity of MR is needed at the time of surgery, and mitral valve repair is performed in 30% to 50% of patients undergoing EVCPP.
3. EVCPP results in improved LVEF, end-diastolic and end-systolic volume indices for LV volumes, and improvement in New York Heart Association (NYHA) functional class.
   a. In a series of patients with advanced heart failure, the event-free survival rate was 98% at 1 year, 95.8% at 2 years, and 82.1% at 5 years.
   b. Independent predictors of mortality include higher preoperative NYHA class, lower LVEF (< 30%), higher end-systolic volume index, and remote asynergy.
   c. Interestingly, the STICH trial demonstrated that despite the reduced LV volume, there was no difference in symptoms, exercise tolerance, hospitalization, and death in patients who received CABG with surgical ventricular reconstruction versus CABG alone. On the basis of this trial, surgical ventricular reconstruction may not add any benefit to HF patients with documented ischemia who are on optimal medical management.

C. Partial LV resection (i.e., **Batista procedure**) involves the resection of myocardium at the posterolateral wall between the anterolateral and the posteromedial papillary

muscles in nonischemic cardiomyopathy, with or without mitral annuloplasty or mitral valve replacement. For the reasons previously stated, this procedure is no longer performed.

D. Dynamic cardiomyoplasty

1. The procedure involves the mobilization of the entire latissimus dorsi muscle to be used as a pedicle graft. The muscle is passed into the thoracic cavity through a window created by removing the left second rib. The muscle is wrapped around the heart and anchored posteriorly, adjacent to the right atrium and pulmonary artery, and anteriorly around the right ventricle.
   a. Sensing electrodes are placed epicardially on the right ventricle, and intramuscular stimulator electrodes are placed in the latissimus muscle.
   b. The muscle conditioning process takes place 2 weeks after surgery and involves the delivery of a single pulse with every other cardiac cycle for 2 weeks. The signal is then incrementally increased every 1 to 2 weeks for 12 weeks.
2. Cardiomyoplasty is believed to work by systolic augmentation of the failing left ventricle and the girdling effect of the muscle acting as an elastic constraint. This prevents LV dilation and improves symptoms, but has no proven survival advantages. Indeed, early mortality is high, especially in those with NYHA class IV status. This procedure is rarely performed now, and data are lacking on its long-term efficacy.
3. Approximately 80% to 85% of surviving patients show NYHA class improvement (mean 1.4 classes). A phase II multicenter FDA study demonstrated significant improvement in LVEF, LV stroke work, and stroke index.
4. Mortality of surgery for class III patients has been < 10%.
5. Hypertrophic obstructive cardiomyopathy is considered to be a relative contraindication.

V. CIRCULATORY SUPPORT DEVICES (I.E., MECHANICAL ASSIST DEVICES)

A. Background

1. Mechanical circulatory assistance is necessary for patients with hemodynamic compromise that are unlikely to survive without a transplant or advanced salvage therapies. Mechanical circulatory support devices may help bridge the patients to recovery or transplantation.
2. The types of devices include the following: intra-aortic balloon counterpulsation pump (IABP), extracorporeal membrane oxygenation (ECMO), univentricular and biventricular nonpulsatile and pulsatile ventricular assist devices (VADs), and the TAH.
3. The decision about which device to use is based on the predicted duration of use, the reversibility of the underlying condition that caused cardiogenic shock, need for single-chamber versus dual-chamber support, and the patient's size.

B. Patient selection

1. Mechanical support is generally indicated in patients who have an inability to maintain hemodynamic stability despite maximal pharmacologic support and who usually must meet criteria as candidates for cardiac transplantation:
   a. Systolic blood pressure < 75 to 80 mm Hg
   b. Cardiac index of < 1.5 to 1.8 L/min/m^2
   c. Pulmonary venous saturation < 50%
2. Indications for short-term circulatory support devices include the following:
   a. Cardiogenic shock after cardiac surgery
   b. Acute myocardial infarction with cardiogenic shock
   c. Acute (fulminant) myocarditis
   d. Cardiac arrest as a complication of interventional cardiac procedures (associated with high mortality and poor survival rates)

3. The 2006 International Society for Heart and Lung Transplantation (ISHLT) guidelines for cardiac transplant candidates:
   a. The most recent ISHLT recommendations give a class I recommendation to thoroughly evaluate other clinical risk factors prior to device implantation. For instance, an inverse relationship between outcome and age > 60 to 65 years has been reported. However, age by itself should not be a contraindication to implantation.
   b. Patients with serum creatinine > 3.0 mg/dL are at higher risk but may be considered candidates for implantation if renal failure is acute and recovery is likely (class I).
   c. Pulsatile intracorporeal devices should only be implanted in patients with body surface area (BSA) > 1.5 m^2.
   d. In patients with abnormal liver function tests secondary to right ventricular (RV) failure, biventricular support should be considered. In addition, biventricular support should be considered in those with irreversible pulmonary hypertension, RV failure, or multiorgan dysfunction.
   e. Active infection should be identified and treated before implantation.
4. If recovery is anticipated, the best option is to use the least traumatic, least complicated device for the individual patient. If recovery of ventricular function is not expected, patients should be considered for the use of a long-term implantable device.

C. Short-term devices

1. Intra-aortic balloon counterpulsation pump

   a. IABP should be placed percutaneously under fluoroscopy so that the tip is about 2 cm below the left subclavian. Height of the patient will determine the size of the IABP (40 cc balloon for the average-sized male). Swan-Ganz catheter and arterial line are encouraged and typically required for hemodynamic monitoring.
   b. IABP enhances coronary blood flow during inflation and decreases oxygen demand by reducing systolic pressure and LV wall stress during deflation. As a result, myocardial consumption and cardiac work are decreased while cardiac output is increased.
   c. Indications: Cardiogenic shock, severe mitral stenosis, decompensated critical aortic stenosis, ventricular septal defect/rupture, refractory ischemia, ischemia ventricular tachycardia, and bridge to definitive therapy.
   d. Contraindications: Hemodynamically significant aortic insufficiency (≥3+), abdominal or thoracic aortic aneurysm/dissections, severe coagulopathy, and sepsis.

2. Extracorporeal membrane oxygenation

   a. ECMO is an extracorporeal system that uses a centrifugal pump to drive blood from the patient to a membrane oxygenator system for carbon dioxide and oxygen exchange.
   b. The femoral artery and vein are cannulated for peripheral access, but the aorta and right atrium can be used as well. The blood is driven from the venous system to the pump and oxygenator and then back into the arterial system.
   c. The device requires systemic anticoagulation and may cause substantial trauma to blood components.
   d. ECMO has the advantage of providing oxygenation in the presence of severe pulmonary dysfunction resulting in hypoxemia. It can also unload both the right ventricle and left ventricle.
   e. The large number of possible complications makes ECMO suitable only for short-term use. It is generally used as a bridge to transplantation, VAD implantation, or other types of definitive therapy.

3. **Percutaneous LV support devices** (TandemHeart, Reitan Catheter Pump, and Impella Recover) are indicated only for short-term use (up to 5 days) and are similar to an IABP with respect to decreasing afterload and myocardial oxygen consumption. Unlike an IABP, these devices completely unload the ventricle rather than simply augmenting it.
   a. The Impella (LP2.5 and LP5.0) is a catheter-based system inserted through the femoral artery that provides hemodynamic support by an axial pump. Blood is pumped directly from the left ventricle to the ascending aorta.
   b. The Impella LP2.5 and LP5.0 can provide cardiac output support of up to 2.5 and 4.5 L/min, respectively, depending on the maximum speed of the rotor.
   c. The TandemHeart system is an extracorporeal continuous-flow centrifugal assist device that provides hemodynamic support via a left atrial-to-femoral bypass with up to a maximum cardiac output of 5.0 L/min. Oxygenated blood is withdrawn from the left atrium via a transseptal cannula and pumped into the femoral artery.
   d. Both systems require anticoagulation with heparin, prolonged supervision, and bed rest.
   e. Hemodynamic support from the Impella and TandemHeart can be continued for up to 5 days.
   f. These devices can potentially be used to support patients with acute MI with cardiogenic shock, patients with decompensated heart failure with myocarditis, and during high-risk percutaneous coronary intervention or valvuloplasty. The TandemHeart can be used for RV support if the catheters are placed so as to pump from the right atrium to the pulmonary artery.
   g. Recent trials for the Impella 2.5, namely, PROTECT I, ISAR-SHOCK (vs. IABP), AMC-MACH2 (vs. IABP), PROTECT II (vs. IABP), RECOVER II (vs. IABP), and EUROPELLA, demonstrated more favorable hemodynamics, reduction in infarct size, as well as reduction in 30-day major adverse cardiac event.
   h. There is a paucity of data regarding clinical outcomes and safety of patients with TandemHeart despite this being commercially available since 2004.
   i. See Table 12.1 for contraindications and potential adverse events.

TABLE 12.1 Contraindications to and Cautions with Percutaneous Left Ventricular Support Devices

Devices	Contraindications	Potential adverse events
Impella	Mural thrombus in the left ventricle, mechanical aortic valve, constrictive heart device, severe peripheral arterial disease, moderate to severe aortic stenosis (≥2+) and regurgitation (≥2+), severe aortic tortuosity, and calcification	Aortic regurgitation, aortic valve injury, arrhythmias, bleeding, tamponade, infection, stroke/transient ischemic attack, hemolysis, limb ischemia
TandemHeart	Moderate to severe aortic stenosis (≥2+) and regurgitation (≥2+), severe peripheral vascular disease	Bleeding, a femoral arteriovenous fistula, thromboembolic events, atrial septal defect, limb ischemia, wound infection, lymphocele, hypothermia

4. **Centrifugal pumps** such as the BioMedicus Biopump are extracorporeal and are commonly used for biventricular support for small patients (BSA ≤ 1.5 m^2) and also with ECMO.
   a. The nonpulsatile pump uses a spinning chamber to generate blood flow through rotating cones or by an impeller mechanism.
   b. The cannulation site for inflow into the pump is the femoral vein, right atrium, or ventricle, and the outflow cannula is placed in the femoral artery, axillary artery, or aorta. The lines are typically left between an unclosed sternum with only skin closure. This necessitates continuous supervision by trained staff and limits the devices to short-term use only.
   c. Heparin anticoagulation is needed.
5. **Pulsatile pumps** are extracorporeal, asynchronous pumps (e.g., Abiomed BVS5000) that are commonly used for right, left, or biventricular support.
   a. There are atrial and arterial cannulas. The atrial cannula is put into the right or left atrium, and the arterial cannula is in the aorta. The advantage over centrifugal systems is that subcostal lines allow sternal closure.
   b. The pump has an upper chamber and a lower chamber. The upper chamber is filled passively by continuous blood flow from the atrium. The lower chamber has two trileaflet polyurethane valves (i.e., inflow and outflow valves) and is designed to eject a stroke volume of approximately 80 mL.
   c. The pump is pneumatically driven by compressed room air and provides 4 to 5 L/min of pulsatile flow.
   d. Anticoagulation is recommended with heparin or warfarin sodium to lower the rate of thromboembolism.
   e. The disadvantages of this system are the lack of mobility and the lower flow rates achieved compared with the chronically implanted devices. A decision is made after 5 to 7 days of support, and if further mechanical support is needed, the Abiomed is removed and a chronic device is implanted.
   f. In small retrospective studies, outcomes in terms of successful bridge to transplantation, pre- and posttransplant mortality, and hospital discharge have not been shown to be significantly different between pulsatile and nonpulsatile devices.
6. **Axial flow pumps**
   a. Nonpulsatile rotary pumps are similar to centrifugal flow devices, but these generate the energy for acceleration of blood by deflecting the flow in the circumferential direction using impellers.
   b. They are smaller and less noisy than other devices, making them a good option for patients with a smaller BSA, as well as potentially decreasing the risk of infection due to smaller pocket size.
   c. Major complications include an increased tendency for pump thrombus, thus mandating anticoagulation and hemolysis.

D. Longer term implantable devices

1. Pulsatile implantable devices: Thoratec paracorporeal system, the CardioWest TAH, Novacor, and HeartMate XVE are currently used.
   a. Thoratec is a paracorporeal system that can be used for left, right, or biventricular support. Because the system is outside the body, it can be used in patients with BSA ≤ 1.5 m^2. However, this does limit mobility and flow rates (maximum stroke volume is 65 mL and flow rates can reach 7.2 L/min). Systemic anticoagulation is required.
   b. The CardioWest TAH is implanted after removal of the native heart and provides complete support. To accommodate the sizable device, patients must have a BSA > 1.7 m^2 and anteroposterior distance of the chest of > 10 cm. Systemic anticoagulation is required. This device has been approved for use as a bridge to transplantation. Another TAH, the Abiocor, is in the

investigational stages of development. This device is smaller and provides more mobility.

c. The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial randomized patients with end-stage heart failure who required ionotropic therapy but were ineligible for cardiac transplantation to a vented electric LVAD or optimal medical therapy. There was a 48% relative reduction in risk of death from any cause in the group that received LVAD compared with the medically treated group. The probability of device failure was 35% at 24 months, and 10 patients had the device replaced. The LVAD group had significant improvement in the quality of life over the trial, but the survival rates with permanent VAD are still far inferior to those for cardiac transplantation. This trial led to the approval of the HeartMate LVAD as a destination therapy in selected patients not eligible for transplant. The follow-up of outcomes in 42 patients who were implanted with destination therapy HeartMate LVAD since the REMATCH trial reveals improved survival rates at 1 month and 1 year and decreased rates of infection and adverse events compared with those found in the trial patients. Occasionally, patients who are implanted with the intent of destination therapy have improvement in conditions such as renal impairment or pulmonary hypertension that had precluded them from eligibility for transplantation earlier in their course and thus are suitable to be reevaluated for transplantation.

2. Axial flow pumps: Jarvik 2000, HeartMate II, and the MicroMed DeBakey.
   a. Produce continuous nonpulsatile blood flow using a small pump with rotor blades. Bearings of the rotor are in direct contact with the blood.
   b. MicroMed and HeartMate II have inflow cannulas that insert in the LV apex. The MicroMed and HeartMate II require a sternotomy and are implanted into a small abdominal pocket. The outflow cannula is attached to the descending aorta.
   c. Jarvik is intraventricular, which eliminates the need for an inlet cannula and eliminates inlet graft kinking, thrombosis, pannus formation in the inlet graft, and inlet obstruction by the septum or lateral wall of the heart. The outflow cannula is attached to the descending aorta. The small size allows the Jarvik to be surgically implanted through a left thoracotomy, with or without cardiopulmonary bypass, and it can be implanted in smaller adults or children.
   d. Axial flow pump is a true LVAD because it augments LV function. Optimal pump speeds are between 8,000 and 12,000 rpm. Native left ventricle is allowed to eject through the aortic valve, giving some pulsatility to the blood flow.
   e. Axial flow pumps can generate flows up to 5 to 7 L/min.
   f. Major complications are thromboembolic events due to inadequate blood flow in the ascending aorta giving rise to thrombus formation and the potential for embolic stroke.
   g. HeartMate II is the best studied LVAD and in turn has become the standard of care in VADs. Miller and colleagues demonstrated the safety and efficacy of the HeartMate II device when used as a bridge to transplantation. Further studies have demonstrated improved quality of life, functional status, and incidence of end-organ failure. Slaughter and colleagues reported a significant improvement in the quality of life and survival free from stroke and device failure with implantation of a continuous-flow LVAD when compared with a pulsatile-flow device for destination therapy.
   h. Data describing experience with the Jarvik 2000 showed that the cardiac index increased by 43%, capillary wedge pressure decreased by 52%, and

80% of the patients improved from NYHA class IV to I. No device thrombosis was reported.

E. Contraindications to VADs

1. Uncontrolled sepsis.
2. Aortic valve incompetence needs to be corrected before implantation of the VAD because it might lead to regurgitation of blood from the outflow cannula back into the left ventricle. Severe mitral stenosis should also be treated to avoid limiting the device output due to decreased native ventricular filling.
3. Preexisting mechanical prosthetic valves may need to be changed to bioprosthetic valves to obviate the need for anticoagulation before implanting the VAD.
4. Hypercoagulable states may preclude the placement of VADs not requiring anticoagulation.
5. Aortic aneurysm or dissection may affect the optimal placement of the outflow cannula in the ascending aorta.
6. Bleeding diathesis.
7. Patent foramen ovale or atrial septal defects need to be closed before implantation of VADs to prevent right to left shunting of blood and paradoxical emboli as the left side of the heart is decompressed.
8. Recent or evolving cerebrovascular accident.
9. Multiorgan failure.
10. Metastatic tumors are an absolute contraindication.

F. Predictors of poor outcomes after implantation of LVADs

1. Age
2. RV failure
3. Urine output < 30 mL/h
4. Central venous pressure > 16 mm Hg
5. Receiving mechanical ventilation
6. Prothrombin time is > 16 seconds; vitamin K is usually given in high doses preoperatively to patients being considered for VAD
7. Reoperation
8. Cachexia syndrome

G. Echo-Doppler assessment of VAD dysfunction. After the implantation of LVAD, intraoperative transesophageal echocardiography is used to assess the following factors:

1. Position of the inflow cannula at the LV apex. If the cannula is angulated toward the interventricular septum, inflow obstruction may result. The velocity of the flow across the inflow cannula is affected by multiple factors, including the flow generated by the device. However, if this velocity is > 2 m/s, then obstruction of the cannula should be considered and thrombus or another mechanical cause of obstruction should be sought.
2. Adequacy of LV decompression.
3. Aortic valve. If the flow rate through the LVAD is adequate, the aortic valve should not open. If there is significant aortic regurgitation, the aortic valve may have to be replaced.
4. Doppler interrogation of the inflow and outflow cannulas is done to exclude inflow and outflow valve dysfunction. Usually, the valves are unable to open, resulting in increased forward flow velocities.
5. Periodic follow-up echocardiographic evaluation is performed to exclude thrombus formation, inflow cannula valve dysfunction, or endocarditis and to evaluate LV systolic function.

H. Right ventricular assist device (RVAD)

1. Decisions for RVAD support (needed by 20% of patients) are based on hemodynamics after LVAD placement. However, implantation of long-term RVAD

devices is more labor intensive and requires long bypass times for placement, which carries higher morbidity.

2. Univariate predictors of RVAD use are small BSAs, female gender, preoperative circulatory support, preoperative mechanical ventilation, and high total bilirubin and aspartate transferase values. Preoperatively, hemodynamic indices of a low mean or diastolic pulmonary artery pressure or a low RV stroke work index (RVSWI < 400 mm Hg · mL/m^2) may indicate the necessity for RVAD after LVAD insertion.
3. Inotropic agents, volume infusions, and vasodilators are used to optimize pulmonary pressures and LVAD flows, with right heart hemodynamic values used as a guide. Aggressive diuresis is often necessary. If VAD flow remains < 2 L/min/m^2, an RVAD system may be placed with the inflow from the right atrium and outflow to the pulmonary artery.
4. Inhaled nitric oxide has gained popularity as a potential alternative to RVAD implantation. In one center, it reduced the need for RVAD support from 7% to 0%.
5. However, the RVAD use is associated with higher incidence of repeat sternotomy for bleeding, and the survival to transplantation is poor at 17%. It may be prudent for patients with risk factors for RV dysfunction to receive a biventricular assist device or a TAH from the start.

I. Complications of VADs

1. **Perioperative bleeding** increases with prolonged cardiopulmonary bypass times and causes excess fibrinolysis and platelet consumption. The degree of bleeding is intimately associated with RV failure and RVAD support. Transfusion is associated with infection and human leukocyte antigen immunization, which can increase the risk of hyperacute humoral rejection for a patient who goes on to transplantation. The use of LVADs increases this risk from 4% to 25% because of the need for perioperative transfusions. Leukocyte-poor blood products should be used to minimize this risk as much as possible.
2. **Gastroinstestinal bleeding** appears to be increased in continuous-flow LVADs in comparison with pulsatile ones, which is thought to be related to decreased levels of large multimers of von Willebrand factor and decreased platelet aggregation. Additional studies have also demonstrated increased incidence of arteriovenous malformations.
3. **Malignant arrhythmias.** There is a high incidence of malignant cardiac arrhythmia after device implantation. Causes include cardiomyopathy, ischemia, chamber dilation, use of inotropic agents, and focal abnormalities at the sewing ring.
4. **Infection.** Antibiotic prophylaxis should be administered to prevent infection. In the long term, there is a 25% to 45% rate of infection, which temporarily removes 20% of patients from the active transplantation list. The most serious infection is VAD endocarditis, which carries a 50% mortality rate and necessitates removal or replacement of the device.
5. **Embolic complications.** Thromboembolism still occurs at a high rate despite appropriate anticoagulation. The Thoratec device carries a 22% risk for cerebrovascular embolic events; the Novacor, 10%; and the HeartMate, 3% to 5% over a 1-year period.
6. **Aortic valve fusion and aortic insufficiency** may develop in patients with continuous-flow LVAD. In a small series of patients who received LVADs for bridge to transplant, examination of the explanted hearts demonstrated some degree of commissural fusion. Echocardiograms of those patients prior to explant demonstrated an increased incidence of aortic insufficiency during LVAD therapy. It is thought that the combination of valve fusion and continuous high pressure on the valve may contribute to the development of aortic insufficiency.

7. **RV failure** is responsible for significant morbidity and mortality after the institution of LVAD therapy. The complex pathophysiology resulting in RV failure includes RV myocardial dysfunction, changes in RV afterload, and interventricular dependence. Risks for the development include biochemical signs of congestions (elevated total bilirubin and aspartate aminotransferase/alanine aminotransferase), decreased RVSWI, increased pulmonary vascular resistance, female gender, smaller patients, and pre-LVAD support. Therapies include inotropic support as well as right-sided mechanical support.

J. Bridging to transplantation. Patients presenting with severe, refractory low cardiac output states need mechanical support as a bridge to transplantation. However, it has been recognized that major end-organ dysfunction affects the survival after transplantation. Mechanical support of the failing heart using short-term circulatory support devices can permit time to assess the reversibility of major organ dysfunction and allow a full workup for the suitability of cardiac transplantation. If the patient meets the selection criteria found in Table 12.2, full LVAD support can be implemented, and if the major organ dysfunction normalizes, a successful bridge to transplantation can be expected. It is expected that 70% to 80% of patients with an LVAD can be successfully bridged to transplantation, compared with 36% of patients managed on inotropic agents with or without an IABP, and 80% of these transplant patients will survive to be discharged from hospital. The percentage of transplant patients requiring mechanical support has increased steadily from 3% in 1990 to > 28% in 2004. Most LVAD implantations (75%) are performed with the strategy of bridge to transplantation. For those with biventricular failure that necessitates mechanical support, the options are combined RVAD and LVAD therapy or support with a TAH. The CardioWest TAH has been approved as a bridge to transplantation therapy.

TABLE 12.2 Patient Selection Criteria for Ventricular Assist Device Support as a Bridge to Cardiac Transplantation

1. Upper age consistent with successful cardiac transplantation, usually about age 70 y
2. Lower age limit determined by patient size large enough to accommodate a device
3. Suitable candidate for cardiac transplantation
4. Imminent risk of death before donor heart availability, usually with evidence of deterioration on maximal appropriate inotropic support and/or intra-aortic balloon support
5. General hemodynamic guidelines:
   a. Cardiac index < 1.8 L/min/m^2
   b. Systolic arterial blood pressure < 90 mm Hg
   c. Pulmonary arterial capillary wedge pressure > 20 mm Hg despite appropriate pharmacologic management
6. Adequate psychological criteria and external psychosocial support for transplantation and potentially prolonged LVAD support
7. Informed consent of patient or family
8. Absence of fixed pulmonary hypertension (pulmonary vascular resistance > 6 Wood units)
9. Absence of irreversible renal or hepatic failure (LVAD support not expected to reverse existing renal or hepatic dysfunction)

LVAD, left ventricular assist device.

K. Bridging to recovery. Clinical recovery sufficient to allow mechanical support device removal has been reported in small numbers at a few institutions. In theory, chronic mechanical unloading may permit reverse remodeling with downregulation of collagen production and hypertrophy and decrease in circulating inflammatory cytokines. Likelihood of successful recovery is greater in those with acute nonischemic cardiomyopathy and much less likely in those with chronic dilated cardiomyopathy. Currently, approximately 5% of LVAD implantations are performed with the strategy of bridge to recovery.

CHAPTER 13

Peter Zimbwa

Cardiac Transplantation

I. INTRODUCTION. Christiaan Barnard performed the first cardiac transplant in Cape Town in 1967. Since then, cardiac transplantation has become a well-established therapeutic option for a select group of patients with end-stage heart disease. It offers these patients, who have no other alternatives, a chance for extended survival and improved quality of life. Cardiac transplantation, however, should not be perceived as a curative procedure. Although the patient's primary problem of heart failure is alleviated by a successful transplantation, a new set of potential long-term complications arises primarily owing to the secondary effects of chronic immunosuppression.

Almost 89,000 heart transplants have been reported worldwide to the International Society for Heart and Lung Transplantation (ISHLT) registry since 1983 (1). As reporting to the ISHLT is voluntary, this number underestimates the actual number of cardiac transplants. There has, however, been a reduction in the number of annual heart transplants from a peak of > 4,000 in the mid-1990s to > 3,000 now. With an estimated additional 2,000 heart transplants per year not reported to the ISHLT, the total number of cardiac transplants likely exceeds 5,000 per year worldwide.

In the United States, the United Network for Organ Sharing (UNOS) reports a 10% reduction in cardiac transplantations over the same time period. UNOS is a national organization which, along with local organ procurement agencies, maintains organ transplantation waiting lists, initiates the evaluation of potential organ donors, allocates organs when a donor is identified, and compiles statistics annually on all aspects of the transplant process, including survival. Since 1990, the number of patients listed and waiting for a cardiac transplant in the United States has more than doubled. There is a shortage of donors, and each year 1.5 to 3 times as many patients are listed for cardiac transplantation as there are donors, so this problem is only going to escalate as the population gets older unless there is a significant increase in organ donation. The annual mortality rate while on the waiting list in 2001 was 15%, which has declined continually over the last decade, probably because of improved medical therapy for end-stage congestive heart failure and increased use of implantable cardioverter–defibrillator. As the annual number of cardiac transplantations has declined, wait times have continued to lengthen. The national median waiting time by UNOS status at listing from 2003 to 2004 data is as follows: 49 days for status 1A, 77 days for status 1B, and 308 days for status 2 patients. However, this can be misleading, as patients with different blood types such as blood type O wait significantly longer than other blood types such as blood type AB on average. A blood type O, status 2 patient could easily wait for > 2 years for a cardiac transplantation.

In the last 5 years (January 2005 to June 2009), the primary indication for adult cardiac transplantation has been nonischemic cardiomyopathies (53%), followed by ischemic cardiomyopathies (38%). Valvular heart disease (3%), adult congenital disease (3%), and retransplantation (3%) and miscellaneous causes (< 1%) account for the remainder (1). The average cardiac transplant recipient is male (77.1%), with an average age of 54 years, which reflects the demographics of the patients on the waiting list. The average donor age is 33 years, and donors > 50 years of age, which were rarely reported before 1986, now account for > 12% of all donors. Outcomes of transplantation continue to improve despite transplants performed on older, sicker patients. Recent data show that 44.5% of recipients were on intravenous inotropic support compared with 34% of recipients 10 years ago. Mechanical circulatory support is also more common, with > 31% of patients on some form of mechanical circulatory support at the time of transplantation, including 20.1% with a left ventricular assist device (LVAD) compared with only 15% on mechanical circulatory support (11% with an LVAD) 10 years ago (1). Survival rates post cardiac transplantation have improved from a median of 8.3 years in the 1980s to 13 years for those surviving to 1 year (1). The risk of death is highest in the first 6 months posttransplantation. Pretransplant factors associated with higher risk of mortality in the first posttransplant year include requiring mechanical circulatory support bridging to transplantation, congenital heart disease, and ischemic cardiomyopathy. Other risk factors include hemodialysis, mechanical ventilation, prior blood transfusion, and infection (1).

Because of the scarcity of donor organs and growing transplant waiting lists, it is crucial that cardiac transplant programs adequately screen and properly select potential transplant recipients. Effective use of this limited resource is essential to avoid "wasting" organs that become available for suboptimal recipients.

II. INDICATIONS FOR CARDIAC TRANSPLANTATION

A. Patients should be on optimal medical therapy for congestive heart failure, as recommended by the American College of Cardiology/American Heart Association guidelines, including angiotensin-converting enzyme (ACE) inhibitor, digoxin, diuretic, β-blocker, and spironolactone. If a patient is intolerant to an ACE inhibitor, she or he should be on an angiotensin receptor blocker.

B. Medically reversible causes of decompensated congestive heart failure should be excluded, including hypothyroidism, tachycardia-mediated cardiomyopathy, alcohol abuse, obstructive sleep apnea, hypertension, and medical noncompliance.

C. Surgically reversible causes of decompensated congestive heart failure should be excluded, including valvular heart disease, unrevascularized coronary artery disease with large territories of ischemia or viability, hypertrophic obstructive cardiomyopathy, and LV (left ventricular) aneurysm for which resection would improve overall cardiac hemodynamics.

D. Patients should be too ill or not candidates for cardiac resynchronization therapy. Alternatively, cardiac resynchronization therapy might have failed to improve symptoms or to halt progression of the underlying pathology.

E. If the previous criteria are met, indications for a cardiac transplant evaluation are as follows:

1. Cardiogenic shock requiring mechanical support (i.e., LVAD or intraaortic balloon pump counterpulsation)
2. Cardiogenic shock requiring continuous intravenous inotropic therapy for hemodynamic stabilization
3. New York Heart Association (NYHA) class III or IV congestive heart failure symptoms, particularly if progressively worsening
4. Recurrent life-threatening LV arrhythmias despite an implantable cardiac defibrillator, antiarrhythmic drug therapy (usually amiodarone), or attempted catheter-based ablation, if appropriate
5. End-stage complex congenital heart disease without pulmonary hypertension
6. Refractory angina without potential medical or surgical therapeutic options

III. COMPONENTS OF A CARDIAC TRANSPLANT EVALUATION AND CONTRAINDICATIONS.

The purpose of a cardiac transplant evaluation is to exclude patients with medical and psychosocial comorbidities and to quantify the severity of a patient's cardiac functional impairment. Recommended investigations prior to a transplantation are summarized in Table 13.1 and exclusion criteria for cardiac transplantation are summarized in Table 13.2.

A. **Blood work.** A standard blood work includes a complete blood cell count; a complete metabolic panel, including hepatic enzymes and thyroid function tests; and blood typing and antibody screening. A serologic assessment should also be performed to determine a potential recipient's presensitization to cytomegalovirus (CMV), toxoplasmosis, hepatitis B and C viruses, and human immunodeficiency virus (HIV).

1. Patients who are anemic should have a thorough evaluation, including iron studies and a colon examination. Esophagogastroduodenoscopy and a hematologic evaluation, including a bone marrow biopsy, may also be necessary. Some patients may benefit from erythropoietin treatment to increase red blood cell counts without the need for transfusions that may expose the patient to further antigens.
2. Patients found to have an elevated serum creatinine level should undergo further evaluation to determine its relationship with low renal perfusion. A normal urinalysis result suggests the absence of renal parenchymal disease. This should include an assessment of cardiac hemodynamics and a renal ultrasound to assess renal parenchymal size and the presence of two kidneys without evidence of obstruction.
3. Patients found to have elevated hepatic enzymes should undergo further evaluation to determine the right-sided filling pressures and they should undergo a hepatic ultrasound scan. All patients should have their hepatitis B and C viral serologies assessed.
4. The patient's serum should be screened for antibodies against human leukocyte antigen (HLA) of B and T lymphocytes, drawn from community volunteers representative of the major HLA allotypes. These antibodies are collectively referred to as panel reactive antibodies (PRAs) and are often elevated in multiparous women and patients with multiple transfusions (often perioperatively in the past). Elevated PRA levels (> 10%) necessitate a pretransplant donor HLA crossmatch

TABLE 13.1 Recommended Evaluation prior to Transplantation

Complete history and physical examination
Laboratory investigations:
- Complete blood count with differential and complete metabolic panel
- Thyroid function studies (thyroid-stimulating hormone)
- Liver function panel, creatinine clearance
- Lipid profile, hemoglobin A1c, and urinalysis

Immunologic data:
- Blood type and antibody screen
- Human leukocyte antigen typing
- Panel reactive antibodies' screen

Serology for infectious diseases:
- Hepatitis (HBsAg, HBsAb, HBcAb, and HepCAb)
- Herpes group virus
- Human immunodeficiency virus
- Cytomegalovirus IgG antibody
- Toxoplasmosis
- Varicella and rubella titers
- Epstein-Barr virus IgG and IgM antibodies
- Venereal Disease Research Laboratory or Rapid Plasma Reagin

Cardiovascular investigations:
- Electrocardiogram, chest X-ray, and echocardiogram
- Exercise test with oxygen consumption
- Right and left heart catheterization
- Myocardial biopsy (if indicated, e.g., to rule out infiltrative process such as amyloidosis)

Vascular assessment:
- Carotid Doppler
- Peripheral vascular assessment (ankle–brachial index and/or duplex ultrasound)
- Abdominal ultrasound
- Ophthalmology examination (if indicated, e.g., to rule out diabetic retinopathy)

Cancer screening:
- Prostate-specific antigen (in men if indicated)
- Papanicolaou smear and mammography (in women if indicated)
- Colonoscopy (if indicated)

Psychosocial evaluation:
- Support system
- Substance abuse history (alcohol, tobacco, and drug use)
- Psychiatric history

Baseline investigations:
- Dental examination
- Bone density scan
- Pulmonary function tests

TABLE 13.2 Exclusion Criteria for Cardiac Transplantation

Irreversible pulmonary parenchymal disease
Renal dysfunction with Cr > 2.0–2.5 or CrCl < 30–50 mL/min (unless for combined heart-kidney transplant)
Irreversible hepatic dysfunction (unless for combined heart–liver transplant)
Severe peripheral and cerebrovascular obstructive diseases
Insulin-dependent diabetes with end-organ damage
Acute pulmonary embolism
Irreversible pulmonary hypertension (PVR > 4.0 Wood units after vasodilators)
Psychosocial instability or substance abuse
History of malignancy with probability of recurrence
Advanced age (> 70 y)
Severe obesity
Active infection
Severe osteoporosis

PVR, pulmonary vascular resistance.

and increase the likelihood of it being positive, making waiting times longer and transplantation more difficult. If a patient has elevated PRA levels, an attempt to reduce them before transplantation with intravenous immunoglobulin, plasmapheresis, mycophenolate mofetil (MMF), or cyclophosphamide, alone or in combination, may be considered. Traditionally, each potential recipient would undergo a thorough HLA tissue typing analysis, including a cytotoxicity assay for assistance in matching donor hearts. In this assay, random donor lymphocytes are incubated with recipient sera. Complement-dependent antibody-mediated cytolysis identifies potential donor-specific antibodies present in that recipient. Currently, most programs use flow cytometry to assess preformed antibodies, rather than cytotoxic assays. This allows for the detection of weaker interactions and provides a wider, more efficient screening process.

B. Imaging

1. All patients should undergo coronary angiography or a functional assessment for ischemia and viability. If ischemia or viability can be demonstrated, consideration should be given to percutaneous or surgical revascularization.
2. Bilateral carotid ultrasound scans should be performed in patients with risk factors for atherosclerosis. Select patients with carotid stenoses, who would otherwise be cardiac transplant candidates, may undergo pretransplantation percutaneous or surgical intervention, thereby eliminating this contraindication.
3. Occasionally, an abdominal aortic ultrasound is obtained to rule out an aneurysm, particularly in patients being considered for mechanical support.

C. Functional assessment

1. Metabolic stress testing is performed to assess the severity of cardiac functional impairment. Patients with compensated congestive heart failure and a peak oxygen consumption of < 14 mL/kg/min or < 50% predicted are considered sufficiently impaired for transplantation (2). Adequate patient effort during the stress test can be assessed by the respiratory exchange ratio, which should be > 1.1, indicating the onset of anaerobic metabolism.

2. Generally, a right heart catheterization is performed to assess cardiac hemodynamics and to optimize a patient's medical therapy. Fixed, severe pulmonary hypertension, defined as a pulmonary vascular resistance (PVR) > 4 Wood units, is a contraindication to cardiac transplantation. In this setting, the donor right ventricle will likely immediately fail after implantation because it is not accustomed to high pulmonary pressures. An attempt should be made to medically decrease the pulmonary hypertension with inotropic agents, nitrates, or nitroprusside. Sometimes an LVAD is required to sufficiently decompress the left ventricle to reverse the pulmonary hypertension. Rarely, endomyocardial biopsy (EMB) is performed, except when an infiltrative cardiomyopathy is suspected.
3. Pulmonary function tests are performed to exclude patients with significant chronic obstructive or restrictive pulmonary disease.
4. Peripheral vascular studies may be obtained to exclude patients with significant peripheral arteriosclerosis obliterans.

D. Comorbidities and implications of heart transplant listing. Advanced age, cancer, and obesity are the three common comorbidities that remain somewhat controversial with respect to their impact on whether an individual program will list a patient for heart transplantation.

1. Age criteria for eligibility were initially quite rigorous; however, it has become apparent that **chronologic and physiologic age are often discrepant**. Most centers do not have a fixed upper age limit, but generally patients > 65 years of age are very carefully screened to rule out comorbidities. ISHLT recommends considering patients for cardiac transplantation if they are ≤70 years of age (3). Patients > 70 years of age may be considered for cardiac transplantation at the discretion of the transplant program and should theoretically be in excellent health except for heart disease. An alternate type of program has been proposed for these patients, whereby older donor hearts would be utilized in this population (3).
2. Active **malignancy** other than skin cancer is an absolute contraindication to cardiac transplantation due to limited survival rates. Chronic immunosuppression is associated with a higher than average incidence of malignancy and is associated with increased recurrence of prior malignancy. Patients with cancers that have been in remission for ≥5 years and patients with low-grade cancers such as prostate cancer are generally accepted for transplant evaluation. Preexisting malignancies are heterogeneous in nature and some are readily treatable with chemotherapy. Thus an individualized approach to these patients is required, and consultation with an oncologist regarding prognosis is often very helpful.
3. Traditionally, centers have been cautious when considering **obese** patients for transplantation. Most currently available data indicate that patients with a pretransplant body mass index (BMI) > 30 kg/m^2 have poor outcomes following cardiac transplantation, with increased rates of infection and higher mortality rates. However, this area remains controversial and some recent data presented in abstract form only demonstrate no significant mortality differences between obese (BMI, 30 to 34.99) transplant recipients and overweight (BMI, 25 to 29.99) transplant recipients. Despite this controversy, the current ISHLT recommendations are that patients achieve a BMI < 30 kg/m^2 or a percent ideal body weight < 140% prior to being listed for cardiac transplantation (3). This cutoff will vary from center to center, but generally a BMI > 35 kg/m^2 will preclude listing for cardiac transplantation.

E. Consultations

1. A **psychosocial assessment** is a crucial component of every cardiac transplant evaluation. Accepted psychosocial contraindications for cardiac transplantations include active smoking; active substance abuse, including alcohol; medical noncompliance; and significant untreated psychologic or psychiatric diagnoses.

Relative psychosocial contraindications to cardiac transplantation include posttraumatic stress disorder and lack of an adequate support structure.

2. For **diabetic patients, an ophthalmology consultation** is obtained for an assessment of retinal end-organ damage related to the diabetes.

IV. UNOS AND THE RECIPIENT LIST. After a patient is accepted as a potential cardiac transplant recipient by a UNOS-certified transplant program, the patient's name is entered on a national list compiled by UNOS. The patient is given a status level based on predefined clinical criteria (Table 13.3), which can be adjusted as the patient's clinical situation evolves. A patient's priority on the UNOS list depends on his or her status level and the duration of time on the list. **Highest priority is given to patients with status 1A and those who have been waiting the longest**. A critical patient initially listed as status 1A immediately has a higher priority than a patient with a status 1B, regardless of the duration of time spent as status 1B. Whether a patient is hospitalized or not does not affect priority on the list, other than the fact that hospitalized patients are more likely to be receiving hemodynamic support (mechanical or inotropic) and are

TABLE 13.3 Description of Status Levels in the United Network of Organ Sharing List

Status	Description
1A	Must be an inpatient
	Life expectancy < 7 d
	LVAD and/or RVAD (maximum 30 d)
	VAD-related thromboembolism
	VAD-related infection (including the pocket and the driveline)
	Mechanical failure of VAD
	Total artificial heart
	Extracorporeal membrane oxygenation
	Intraaortic balloon pump with inotropic criteria
	Life-threatening refractory arrhythmias with or without a VAD
	Mechanical ventilation
	High-dose single intravenous inotrope (see doses below) or multiple intravenous inotropes, in addition to Swan-Ganz catheter
1B	Inotrope-dependent
	VAD not meeting criteria for 1A status
2	Not inotrope-dependent
7	Inactive on list because of improved clinical status or short-term contraindications to cardiac transplantation (e.g., active infection)
Inotrope criteria for status 1a	
1.	Two or more inotropes, regardless of dose
2.	Intravenous milrinone, at least 0.5 μg/kg/min by continuous infusion
3.	Intravenous dobutamine, at least 7.5 μg/kg/min by continuous infusion

LVAD, left ventricular assist device; RVAD, right ventricular assist device; VAD, ventricular assist device.

at a higher status level. A hospitalized patient on continuous inotropic therapy has the same status as a similar patient on home continuous inotropic therapy. Patients on home continuous inotropic therapy awaiting cardiac transplantation are generally thought to have an increased mortality related to the proarrhythmic effect of inotropic therapy, and most programs require implantation of an intracardiac defibrillator as a prerequisite for discharge.

V. WORKUP OF A POTENTIAL CARDIAC DONOR. Potential cardiac donors are patients who are declared brain dead but otherwise have viable internal organs. Generally, these are patients with lethal head injuries or catastrophic central nervous system events (i.e., intracranial hemorrhage, stroke, or cerebral anoxia).

A. Declaration of brain death. A neurologist or a neurosurgeon usually declares the brain death of a potential organ donor. Usually, this declaration is made after a period of observation (about 12 hours) during which no neurologic improvement is seen. Physicians involved in the care of potential transplant recipients are not involved in this decision to avoid conflicts of interest. Criteria for the determination of brain death are very specific. Absence of any one of the following criteria makes the patient ineligible for organ donation.

(1) A known cause of death
(2) Absence of hypotension, hypothermia, hypoxemia, and metabolic perturbations
(3) Absence of medical or recreational drugs known to depress the central nervous system
(4) Absence of cerebral cortical function
(5) No response to painful stimuli
(6) Absence of brainstem reflexes
  (a) Pupillary constriction to light
  (b) Corneal reflex
  (c) Vestibular ocular reflexes (i.e., doll's eyes or cold caloric testing)
  (d) Gag reflex
  (e) Cough reflex
(7) Positive apnea test: no spontaneous respiration despite arterial $P_{CO_2} > 60$ mm Hg for at least 10 minutes after disconnection from the ventilator
(8) An electroencephalogram (EEG) is not required but may be performed at the discretion of the examining physician. The EEG should demonstrate electrical silence.

B. Potential donor screening. After a patient is declared brain dead, a local organ procurement organization (OPO), under the auspices of UNOS, performs the initial evaluation of a potential donor. This evaluation includes a thorough patient and family history, focusing specifically on cardiac risk factors and potentially transmittable diseases (i.e., malignancy and infection). Preliminary blood tests are done, including determinations of cardiac enzymes; serologies for hepatitis B and C viruses, HIV, toxoplasmosis, and CMV; ABO blood group typing; and HLA antigen typing. An echocardiogram is routinely performed to assess the cardiac function and to rule out congenital anomalies and valvular disease. At the request of the potential recipient's physician, a coronary angiogram may be obtained if a donor has significant cardiac risk factors, has positive cardiac enzymes, or is relatively advanced in age. Cardiac donor selection criteria are summarized in Table 13.4.

If the potential recipient also has elevated PRA levels, a prospective complement-dependent antibody-mediated lymphocytotoxic crossmatch is usually performed, in which the recipient's serum is incubated with donor lymphocytes to identify potential donor–recipient HLA incompatibility. Many centers today perform a "virtual crossmatch" for patients with elevated PRA levels to improve donor availability. With the HLA technologies available today, the exact antigen specificity of the recipients' anti-HLA antibodies is known. If the HLA tissue typing of the potential donor

TABLE 13.4 Cardiac Donor Selection Criteria

Must meet legal requirements for brain death
No history of chest trauma or cardiac disease
No prolonged hypotension or hypoxemia
Normal ECG
Normal cardiac angiogram, performed if indicated by donor age (male > 45 y or female > 50 y) and history
Negative HBsAg, hepatitis C virus, and human immunodeficiency virus serologies
Systolic blood pressure > 100 mm Hg or mean arterial pressure > 60 mm Hg
Central venous pressure 8–12 mm Hg
Inotropic support < 10 μg/kg/min dopamine or dobutamine
Age < 55 y preferred

ECG, electrocardiogram.

does not include the antigens against which the recipient is sensitized, it is assumed that the actual crossmatch will be negative (i.e., a "virtual" negative crossmatch). If a prospective crossmatch is not performed, a retrospective crossmatch (by lymphocytotoxic assay or by flow cytometry) is performed using donor lymphocytes obtained from donor aortic lymph nodes retrieved at the time of harvest.

C. Donor–recipient matching. UNOS maintains a computerized list of all patients listed and waiting for cardiac transplantation. A list of potential recipients with compatible blood types is generated for each potential donor organ and is made available to the OPO. In this list, priority is given to local patients (defined as within the OPO's territory) with the highest status level who have been waiting the longest. Recent changes to the UNOS donor net criteria mean that a local status 2 patient is no longer higher on the list than a status 1A patient from outside the OPO's territory.

Transplant physicians of the potential recipient may also reject a potential organ because of a positive prospective crossmatch, donor–recipient size mismatch, or a prolonged projected ischemic time (usually related to long-distance travel). Matching donor and recipient size is important, because an oversized donor organ may not allow closure of the chest without compression of the organ and an undersized donor organ may not be able to pump a sufficient quantity of blood. **Current guidelines suggest that the recipient's weight should range between 70% and 130% of a potential donor's weight** (4).

VI. SURGICAL ISSUES RELATED TO CARDIAC TRANSPLANTATION. Most surgical issues related to cardiac transplantation are beyond the scope of this chapter and are mainly of interest to the cardiac surgeon. The main surgical issue of interest to the transplant cardiologist is related to the anastomosis of the right atrium. The surgeon may suture the donor atrium to the recipient atrium (i.e., **biatrial anastomosis**) or suture the donor superior vena cava to the recipient superior vena cava and the donor inferior vena cava to the recipient inferior vena cava (i.e., **bicaval anastomosis**). The bicaval anastomosis approach is more time consuming but reduces the incidence of atrial arrhythmias (including sinus

node dysfunction), reduces the incidence of posttransplant tricuspid regurgitation, and improves right atrial hemodynamics. The bicaval anastomosis approach does, however, provide some potential difficulties to the cardiologist trying to perform surveillance EMBs, because these anastomoses have a tendency to scar and narrow the central lumen over time. Currently, most centers employ the bicaval anastomosis approach, although no survival advantage has been conclusively demonstrated with this approach.

VII. POSTOPERATIVE COMPLICATIONS AFTER CARDIAC TRANSPLANTATION

A. Surgical complications. The most common surgical complication is the development of a **pericardial effusion** with or without tamponade. Pericardial effusions are very common because of the large potential space left behind as the dilated and dysfunctional recipient left ventricle is replaced with a more appropriately sized donor left ventricle. Rarely, pericardial tamponade develops, necessitating percutaneous or surgical evacuation of the pericardium. Other surgical complications are much less common but can be catastrophic and usually result from a problem either at a site of anastomosis or at a site of cannulation.

B. Early graft dysfunction

1. **LV systolic dysfunction.** It is common for transplant recipients to require inotropic support as they come off cardiopulmonary bypass. The most commonly used inotropic agents in this setting are dobutamine, milrinone, and isoproterenol, used alone or in combination. It is also common for transplant recipients to require peripheral vasoconstrictors such as epinephrine, norepinephrine, and dopamine in the early postoperative period, because most are on large quantities of oral or intravenous vasodilators before transplantation. Most patients can be weaned off inotropic therapy and peripheral vasoconstrictors within the first 48 hours.
2. **LV diastolic dysfunction** is very common soon after cardiac transplantation. It usually results from reversible ischemia or reperfusion injury to the donor organ and normally resolves over a period of days to weeks. If the ischemia or reperfusion injury is sufficiently severe to induce significant contraction band necrosis or myocardial fibrosis, as seen on EMB, chronic diastolic dysfunction can ensue. Another potential cause of diastolic dysfunction is donor–recipient mismatch, particularly with a small donor organ or acute rejection.
3. **Right ventricular dysfunction** is much more common than LV dysfunction after cardiac transplantation, especially in patients with preexisting pulmonary hypertension. The right ventricle is subjected to similar ischemic or reperfusion injury risks as the left ventricle. Right ventricular dysfunction is usually accompanied by right ventricular dilation and the failure of coaptation of the tricuspid valve leaflets, leading to severe tricuspid regurgitation. The treatment for perioperative right ventricular dysfunction is usually intravenous milrinone and nitrates to increase cardiac output and lower the PVR. In patients with refractory pulmonary hypertension, other agents to be considered include nitroprusside, nesiritide, isoproterenol, or rarely, inhaled nitric oxide. Usually, the pulmonary hypertension and right ventricular dysfunction improve over a period of days to weeks.

C. Cardiac arrhythmias. Most transplant recipients require perioperative temporary atrioventricular pacing. Sinus node dysfunction is very common, probably because of a combination of surgical trauma, ischemia or reperfusion injury, and denervation. The incidence of sinus node dysfunction is believed to be reduced by the bicaval anastomosis technique compared with the biatrial anastomosis technique. With time, the sinus node usually recovers, and a permanent pacemaker is unnecessary. Preoperative use of amiodarone increases the likelihood of bradycardia after transplantation. Other cardiac arrhythmias are rare, especially off inotropic therapy, and may signify acute rejection.

D. Renal dysfunction. Preoperatively, many transplant recipients have some degree of impaired renal function. There is a risk of worsening renal function perioperatively.

This risk is compounded by the fact that the major immunosuppressive agents (i.e., cyclosporine and tacrolimus) are nephrotoxic. If renal function does worsen postoperatively, induction therapy is begun to delay initiation of cyclosporine or tacrolimus. Most centers no longer use OKT3 for induction therapy but rather use interleukin-2 (IL-2) receptor blockers or thymoglobulin for induction therapy.

VIII. SYSTEMIC IMMUNOSUPPRESSION. Much of the success in cardiac transplantation today is attributed to advances in immunosuppression. However, balancing the risk of allograft rejection against the inherent risk of immunosuppression remains a challenge in transplant medicine. Immunosuppressant protocols during and after cardiac transplantation vary greatly from program to program and even from patient to patient within a program. Triple therapy, which constitutes the cornerstone of modern immunosuppressive regimens in cardiac transplantation, including a calcineurin inhibitor (such as cyclosporine or tacrolimus), a cell cycle–modulating or antiproliferative agent (such as MMF or azathioprine), and a corticosteroid (4), is increasingly being challenged. Recently, the Tacrolimus in Combination, Tacrolimus Alone Compared (TICTAC) trial prospectively randomized 150 cardiac transplant patients in an open fashion to receive either tacrolimus monotherapy or tacrolimus and MMF. Corticosteroids were used in all patients but were successfully discontinued over 8 to 9 weeks. The addition of MMF to tacrolimus did not provide an advantage over tacrolimus alone in terms of primary end point of rejection over the first 6 months, the secondary end points of allograft vasculopathy, and 3-year survival (5). The trial has, however, been criticized for being underpowered to demonstrate true differences in the primary and secondary end points, its use of an unvalidated biopsy grading scale, inconsistent timing of intravascular ultrasound (IVUS), use of higher and potentially nephrotoxic levels of tacrolimus, and the lack of a control arm of routine triple drug immunosuppression for comparison with the two study arms (6). Controversy remains about the advisability of using cytolytic or induction therapy in the nonpresensitized recipient without renal failure (Table 13.5).

A. Steroids. The mechanism by which steroids serve as immunosuppressants is complex and incompletely understood. Steroids bind to nuclear receptors, thereby preventing gene expression of various cytokines important for B-cell and T-cell activation and proliferation, the most important of which is IL-2. Steroids also have important anti-inflammatory properties and suppress macrophage activity. Important side effects of steroids include diabetes, hypertension, weight gain, osteoporosis, and avascular necrosis of the femoral head.

Steroid-dosing protocols vary tremendously from one institution to another. A dose of 500 to 1,000 mg of intravenous Solu-Medrol is usually given to the patient before being brought to the operating room and then 125 to 150 mg is usually repeated every 8 hours for a total of three more doses. At that point, if the patient is extubated, oral prednisone is begun. Some centers start at a divided dose of 1 mg/kg/d and wean by 5 mg daily, whereas others start immediately at only 20 mg daily. The dose of steroid is slowly tapered, provided the patient continues to have a clean biopsy record. The trend in clinical practice is to wean most patients completely off steroids. Some centers continue to advocate the indefinite use of low-dose prednisone (2.5 to 5 mg daily). If a decision is made to withdraw steroids completely, it should be done approximately 1 month before the next scheduled biopsy to ensure continued lack of acute cellular rejection.

Steroids are also given in "pulses" to treat episodes of acute cellular rejection. If a patient has acute cellular rejection associated with hemodynamic compromise, she or he is admitted for 1 g of intravenous Solu-Medrol daily for 3 days and may be given cytolytic therapy or plasmapheresis, or both. If no hemodynamic compromise is associated with the episode of rejection, a daily dose of 100 mg oral prednisone for 3 days is usually sufficient, followed by repeat biopsy, at most 2 weeks later to ensure resolution.

TABLE 13.5 Common Immunosuppressants

	Steroids	Calcineurin inhibitors	MMF	AZA	TOR inhibitors	OKT3	Polyclonal antilymphocyte antibodies	IL-2 receptor blockers
Drugs	Prednisone (P) (po) Solu-Medrol (S) (IV)	Neoral (N) Tacrolimus (T)	—	—	Rapamycin (R) Everolimus (E)	—	Atgam (A) Thymoglobulin (T)	Basiliximab (B) Daclizumab (T)
Indication	Chronic IM, acute rejection	Chronic IM	Chronic IM, skin cancer with AZA	Chronic IM	Chronic IM, vasculopathy	Induction, acute rejection	Induction, acute rejection	Induction
Dosing								
Initial	IV 125–150 mg q8h	N: 100 mg bid T: 2 mg bid	1.5 g bid	1–2 mg/kg/d	R: 2–5 mg qd E: 1.5–3 mg qd	—	—	—
Induction	—	—	—	—	—	5 mg qd × 5–15 d	A: 15 mg/kg/d T: 1.5 mg/kg/d × 5–15 d	B: 20 mg on days 1 and 4 D: 1 mg/kg q1-2wk × 5 doses
Maintenance	Weaned off	Adjusted to levels	1.5 g bid	1–2 mg/kg/d	Adjusted to levels	—	—	—
Acute rejection	P: 100 mg qd × 3 S: 1g IV qd × 3	Consider change from CsA to tacrolimus	—	—	—	As above	As above	—

Target levels	—	See Tables 12.3 and 12.4	2–4 ng/mL, 12-h trough, WBC > 4.0	WBC > 3.0	R: 4–12 ng/mL, 18-h trough	CD3 count < 20 cells/mL	CD3 count < 20 cells/mL	—
Common side effects	Diabetes, osteoporosis, weight gain, hypertension, and adrenal insufficiency	Nephrotoxicity, hypertension, tremors, and gingival hyperplasia	Diarrhea, nausea, and myelosuppression	Myelosuppression, skin cancer	Hypertriglyceridemia and thrombocytopenia	Cytokine release, hypotension, capillary leak syndrome, PTLD, and CMV superinfection	Thrombocytopenia, fevers, chills, PTLD, and CMV superinfection	—
Common drug interactions	—	Erythromycin, diltiazem, verapamil, rapamycin, anticonvulsants, rifampin, and statins	Cholestyramine and probenecid	Allopurinol	Cyclosporine	—	—	—

AZA, azathioprine; CMV, cytomegalovirus; CsA, cyclosporin A; IL, interleukin; IM, immunosuppression; MMF, mycophenolate mofetil; PTLD, posttransplant lymphoproliferative disorder; TOR, target of rapamycin.

B. Calcineurin inhibitors. Calcineurin is a phosphatase enzyme that triggers transcription of new messenger RNA after activation of the T-cell receptor by an appropriate antigen, leading to increased gene expression of IL-2 and other important cytokines. Calcineurin antagonists inhibit this phosphatase activity, thereby preventing the synthesis of these cytokines, which prevent B-cell and T-cell proliferation.

1. **Cyclosporine** (Neoral, Gengraf, and Sandimmune) is a calcineurin antagonist with a highly variable pattern of bioavailability, depending on the oral formulation taken. Bioavailability of the original soft gelatin capsule (Sandimmune) was low and depended on emulsification by bile salts. The newer microemulsion formulation (Neoral) does not depend on bile salts for emulsification and has a more consistent bioavailability. Nevertheless, there remain tremendous interpatient differences in bioavailability, and dosing of Neoral is primarily based on serum drug trough levels. Because of the narrow therapeutic range of cyclosporine, drug trough levels are also important to prevent toxicity. Nephrotoxicity is the most important side effect of cyclosporine therapy and is related to renal afferent arteriolar vasoconstriction and the resultant reduced renal perfusion. Other side effects include systemic hypertension, gingival hyperplasia, and tremors. Calcium channel blockers, particularly diltiazem, reduce hepatic metabolism of cyclosporine, thereby increasing serum drug levels. This drug interaction is frequently used clinically to reduce the oral dose of cyclosporine required to achieve a given serum drug concentration, thereby minimizing the cost of immunosuppression.

   Postoperatively, once the patient is hemodynamically stable with good urine output, cyclosporine is initiated via continuous infusion at 1 mg/h. When the patient is able to take oral medicines, Neoral is begun at a dose of 100 mg twice daily, with adjustments in the dose based on serum trough levels (Table 13.6). The dose of Neoral is gradually reduced over a period of 1 year if the patient has a clean biopsy record.

2. **Tacrolimus** (Prograf), previously known as FK506, is another calcineurin inhibitor that has low oral bioavailability. Tacrolimus has never been prospectively shown to be superior to cyclosporine in the prevention of acute cellular rejection. However, it has become a standard practice to change cyclosporine in a patient's immunosuppressive regimen to tacrolimus in the setting of recurrent or persistent acute cellular rejection with adequate cyclosporine levels. Some programs empirically use tacrolimus for all female patients because a common side effect of cyclosporine is hirsutism. The major side effects of tacrolimus are nephrotoxicity and neurotoxicity (most commonly tremor).

   Like cyclosporine, tacrolimus is initiated postoperatively once the patient is hemodynamically and renally stable. A dose of 0.01 mg/kg/d of tacrolimus is administered by continuous infusion. Unfortunately, intravenous tacrolimus is seemingly more nephrotoxic than cyclosporine. Tacrolimus can be given sublingually using an oral to sublingual dose ratio of 1:1. After the patient starts taking

TABLE 13.6 Target Serum Cyclosporin A Levels

Time	Target level (12-h trough)
0–3 mo	250–350 ng/mL
3–12 mo	200–250 ng/mL
>12 mo	150–175 ng/mL

TABLE 13.7 Target Serum Tacrolimus (FK506) Levels

Time	Target level (12-h trough)
0–30 d	12–20 ng/mL
1–6 mo	8–15 ng/mL
6–18 mo	5–15 ng/mL
>18 mo	5–10 ng/mL

medicines orally, the dosage of tacrolimus is changed to 0.5 to 2 mg twice daily, with dose adjustment based on serum FK506 levels (Table 13.7).

C. Mycophenolate mofetil (CellCept). MMF inhibits DNA synthesis by inhibiting de novo purine synthesis. Because human lymphocytes depend on the de novo synthesis of purines for DNA replication, MMF has the unique ability to inhibit B-lymphocyte and T-lymphocyte proliferation without affecting DNA synthesis in other cell lines, which can obtain purines through the parallel and unaffected purine salvage pathway. MMF has become the preferred immunosuppressant over azathioprine at most transplant centers because of a reduced mortality rate at 1 year (6.2% vs. 11.4%; $p = 0.03$), especially among patients with treated biopsy-proven rejection and severe hemodynamic compromise (32% vs. 0%). Although there is a trend toward a reduced incidence of grade 3A (now 2R) rejection in MMF-treated patients compared with azathioprine-treated patients, it did not reach statistical significance (45% vs. 52.9%; $p = 0.055$). The main disadvantage of MMF over azathioprine is the increased cost (almost 10-fold) and the potential increased risk of opportunistic viral infections. Toxicities of MMF include gastrointestinal symptoms (nausea, vomiting, and diarrhea) and myelosuppression. Some patients on MMF develop clinically significant leukopenia, necessitating dose reduction or discontinuation of the drug. The incidence of these adverse events is higher in patients receiving > 3 g/d of MMF. Most symptoms will resolve with the reduction of dose.

MMF is given intravenously or orally. Because of the high bioavailability (> 90%), the initial dose of MMF is 1 g taken twice daily, regardless of the route of administration. The initial dose is given within the first 12 hours after transplantation. Few centers monitor the serum levels of mycophenolic acid (MPA), the active metabolite of MMF. The serum levels of MPA are higher when MMF is administered with tacrolimus compared with cyclosporine; therefore, it may be advisable to empirically reduce the dosage of MMF when switching from cyclosporine to tacrolimus. Although there is no consensus on dose adjustment of MMF, at the Cleveland Clinic, the dose is adjusted to maintain MPA 12-hour trough concentrations in the range of 2 to 4 µg/mL.

D. Azathioprine (Imuran) is a purine analog that impairs DNA synthesis, thereby preventing B-lymphocyte and T-lymphocyte proliferation in response to antigen stimulation. Azathioprine has largely been replaced by MMF as the antiproliferative agent of choice in the triple immunosuppressant cocktails of today. Because there is no drug level assay available, azathioprine dosing is usually fixed between 1 and 2 mg/kg/d. The major side effect of azathioprine is myelosuppression, and the dose of azathioprine is usually adjusted to maintain a white blood cell count of > 3,000/mL. Azathioprine is metabolized by xanthine oxidase, and xanthine oxidase inhibitors such as allopurinol can lead to the accumulation of toxic levels of azathioprine and profound and prolonged myelosuppression.

E. Inhibitors of the target of rapamycin (TOR) enzyme: sirolimus (Rapamune) and everolimus (Certican, previously known as RAD). Immunosuppressants have been developed that inhibit the enzyme TOR. TOR is activated after IL-2 stimulation of the T-cell IL-2 receptor and is critical for lymphocyte growth and proliferation. In contrast to calcineurin inhibitors, inhibitors of TOR do not block cytokine production (e.g., IL-2) but rather block the cellular response to these cytokines. TOR inhibitors also inhibit vascular smooth muscle cell growth and proliferation in response to various growth factors. It is hoped that this property of TOR inhibitors will help reduce the rate of progression of chronic transplant coronary vasculopathy. Unlike calcineurin inhibitors, TOR inhibitors are not nephrotoxic. When used in combination with cyclosporine, TOR inhibitors appear to act synergistically with regard to immunosuppression. However, worsening of renal function is common but can be prevented by lowering the cyclosporine dose without worsening of immunosuppression. The main side effects of this class of compounds are significant hypertriglyceridemia and thrombocytopenia.

Sirolimus and everolimus are both TOR inhibitors. They are structurally similar, but everolimus has a much higher bioavailability than sirolimus. The appropriate dosing of these agents remains unclear, but for sirolimus, it is probably 1 to 5 mg/d, and for everolimus, it is probably 1.5 to 3 mg/d. Sirolimus appears to lower the incidence of acute cellular rejection in humans (7) and to slow the progression of transplant vasculopathy (8). Preliminary human studies using intravascular coronary ultrasonography have also shown a reduction in neointimal proliferation with both sirolimus and everolimus.

It remains unclear where TOR inhibitors will fit in with current immunosuppressive protocols. The most likely scenario is their use in combination with a calcineurin inhibitor and prednisone, in place of MMF or azathioprine. Alternatively, they could be used in place of calcineurin inhibitors and in combination with MMF or azathioprine and prednisone, particularly in patients with either preexisting or worsening renal dysfunction.

F. Induction therapy and therapy for steroid-resistant acute rejection. The purpose of induction therapy is to deplete T lymphocytes or to prevent lymphocyte proliferation during the most immunoreactive phase, which occurs immediately after transplantation. Induction therapy has continued to be a subject of controversy in heart transplantation for more than 20 years. Induction therapy is not routinely used in posttransplant patients because of a lack of evidence of improved survival or less acute rejection. The two clear indications to use induction therapy are as follows: (1) in patients who have severe renal dysfunction, which precludes the introduction of calcineurin inhibitors within the first 2 days following transplantation and (2) in patients who have acute graft failure secondary to an immune mechanism such as with hyperacute rejection or humoral rejection. The two scenarios in which induction therapy is often used are in patients with preexisting significant renal dysfunction and in significantly presensitized patients.

The principle behind the treatment of steroid-resistant acute rejection is similar, in that the depletion of activated T lymphocytes presumably prevents further clonal expansion of the antigen-activated offending lymphocyte population.

1. **OKT3** (Muromonab-CD3) is a murine-based monoclonal anti-CD3 antibody. The CD3 antigen is part of the T-cell receptor complex present on activated, circulating T lymphocytes. OKT3 binds to the CD3 antigen and produces cell death by multiple mechanisms or T-cell receptor internalization, thereby inactivating the lymphocyte.

   The dose of OKT3 is 5 mg/d, for a total of 5 to 10 days. After a course of OKT3, there is an immediate and well-recognized rebound in CD3-positive (activated) T-lymphocyte counts that can lead to acute cellular or humoral rejection. Cytokine release syndrome frequently occurs and typically begins 30 to 60 minutes after administration of a dose of OKT3 and may persist for

several hours. Premedication with acetaminophen, steroids, and antihistamines may help minimize symptoms. CD3+ T cells are generally undetectable during OKT3 therapy; however, within 12 to 24 hours after cessation of OKT3, CD3+ T cells reappear in circulation, unlike after treatment with antithymocyte globulin (ATG) preparations, with which the lymphocyte depletion is present for weeks. Therefore, many programs prophylactically increase the steroid dose during withdrawal from OKT3. Since OKT3 is a murine-based monoclonal antibody, patients may develop antibodies toward the mouse component of the antibody that may limit the effectiveness of future courses of OKT3. Patients treated with OKT3 have had an increased incidence of posttransplant lymphoproliferative disorder (PTLD) and lymphoma with a cumulative dose of > 75 mg. Opportunistic viral infections are also more common after OKT3 therapy.

2. **Polyclonal antilymphocyte antibodies** are produced by injecting animals with human lymphocytes or thymocytes and then collecting the animal's serum. Two commercially available formulations are antithymocyte globulin (Atgam), which is horse-based, and Thymoglobulin, which is rabbit-based. The antibodies produced in this manner are directed against a variety of targets on the surface of B and T cells and induce complement-mediated lymphocytolysis. The recommended doses of Atgam and Thymoglobulin are 15 mg/kg/d and 1.5 mg/kg/d, respectively, for a total of 7 to 10 days. Adequate lymphocyte depletion can be ensured by quantifying the CD2-positive lymphocytes, a marker present on all lymphocytes. Similar to OKT3, immunity may develop to the animal component of these antibodies, rendering them ineffective if further courses of therapy are necessary. An increased incidence of PTLD, lymphoma, and opportunistic viral infections has also been observed. Patients receiving either formulation are often prophylactically treated with ganciclovir to prevent CMV infection.
3. **IL-2 receptor blockers** are competitive fully humanized monoclonal anti-CD25 antibodies. CD25 antigen is the IL-2 receptor and is only present on the cell surface of activated T lymphocytes. In contrast to OKT3, there is no initial receptor agonist phase and no cytokine release syndrome.

   For the two commercially available IL-2 receptor blockers, basiliximab (Simulect) and daclizumab (Zenapax), there are data to support the use of daclizumab only for induction therapy after cardiac transplantation, particularly in patients with preexisting renal dysfunction in whom calcineurin inhibitor avoidance is preferable in the early postoperative period. Fewer patients treated with daclizumab, in addition to standard triple immunosuppressant therapy, developed acute rejection compared with controls (9). Patients treated with daclizumab also had a lower severity and frequency of acute rejection during the first 3 months and had a longer time to the first episode of rejection. In contrast to other agents used for induction therapy, daclizumab does not appear to increase the risk of lymphoma, PTLD, or opportunistic viral infections. The serum half-life of daclizumab is 21 days, and dosing strategies call for a dose of 1 mg/kg every 1 to 2 weeks after transplantation, for a total of five doses (including the initial dose). There is no indication for either basiliximab or daclizumab as therapy for steroid-resistant persistent acute rejection. Given the virtual absence of side effects from IL-2 receptor blockade, the critical issue that needs to be addressed for these agents to become widely used clinically is whether the reduction in early acute rejection episodes translates into improved long-term survival and a reduction in transplant coronary vasculopathy.

IX. REJECTION. In the ISHLT registry, 30% of the cardiac allograft recipients between January 2003 and June 2008 experienced rejection during the first year. Females and young patients were at higher risk than males and older patients, respectively. Allograft rejection involves both the cellular and humoral arms of the adaptive response. An ideal immune monitoring strategy has been described as the one that would be noninvasive,

TABLE 13.8 Grading Scale (2004) for Endomyocardial Biopsies

Grade	Severity of cellular rejection	Histologic findings
1R[a]	Mild	Interstitial and/or perivascular infiltrate with up to 1 focus of necrosis
2R	Moderate	≥2 foci of infiltrate with associated necrosis
3R	Severe	Diffuse infiltrate with multifocal necrosis ± edema ± hemorrhage ± vasculitis

[a]R = revised.

would reliably distinguish between the presence and absence of rejection, and would detect overimmunosuppression (10). Such a strategy does not, however, exist. The immunologic status of a transplant recipient is currently monitored by immunosuppressant drug levels, echocardiographic assessment of allograft function, and EMB. Noninvasive monitoring therapies have been tested in the hope of overcoming these limitations. Gene expression profiling (GEP) test, which is also known as the AlloMap test, and cardiac magnetic resonance (CMR) imaging are examples of promising alternatives that are being evaluated.

A. Endomyocardial biopsy. The current gold standard of rejection surveillance after cardiac transplantation is EMB. However, EMB is invasive, inconvenient, expensive, and subject to sampling error and interobserver variability. Rejection of the cardiac allograft is usually clinically silent unless it is accompanied by significant hemodynamic compromise (i.e., congestive heart failure). As a result, EMBs are routinely performed for rejection surveillance (see Chapter 63). To mitigate the interobserver variability, the ISHLT revised and simplified the grading criteria for acute cellular rejection (Table 13.8) (11). Because the likelihood of acute rejection is highest early after transplantation, the frequency of biopsies is high during this period and then gradually tapers off, depending on the results (Table 13.9).

B. Surrogate markers of rejection

1. **Peripheral biomarkers.** While high levels of circulating pretransplant, donor-specific antibodies to HLAs have been demonstrated to predict greater risk of severe

TABLE 13.9 Endomyocardial Biopsy Schedule

Weeks after transplantation	Biopsy frequency
1–4	Weekly
5–12	Every 2 wk
13–24	Monthly
25–52	Every 2 mo
Year 2	Every 3–4 mo
Years 3–4	Every 6 mo
>4 y	Only if clinically indicated
After biopsy with acute rejection	2 wk after initial biopsy

rejection, no peripheral markers have been shown to reliably correlate with allograft rejection posttransplantation among those evaluated, including cytokine levels, markers of myocardial necrosis (CK-MB and troponin), complement fragments, prothrombin, P-selectin fragments, CD69 membrane protein, soluble CD30, endothelin, serum nitrate, thromboxane A_2, matrix metalloproteinase-1 in brain, vascular endothelial growth factor, natriuretic peptide, and C-reactive protein (12).

2. **Echocardiography.** Echocardiography is ubiquitous in cardiac transplant centers, drawing investigative attention to it as a noninvasive surveillance alternative to EMB for cardiac allograft rejection. For it to be a useful screening tool, however, echocardiography must identify graft rejection before global LV systolic dysfunction ensues. The challenge has been to identify such sentinel markers. Myocardial performance index, pressure halftime, intraventricular relaxation time, and acoustic quantification of cardiac filling volumes have not shown consistency. Changes > 10% in serial measurements of pulsed wave tissue Doppler measurements of early diastolic basal posterior wall motion velocity were able to exclude clinically relevant rejection with positive predictive value and negative predictive value of 92% and 95%, respectively. Technical limitations with this technique in the cardiac transplant population together with inconsistent observer interpretation have meant that echocardiography is neither sufficiently sensitive nor specific to supplant routine EMB (12).
3. **Gene expression profiling.** GEP is a new modality for surveillance of cardiac allograft rejection. **This test uses microarray and quantitative polymerase chain reaction (PCR) of peripheral blood mononuclear cells to measure the expression of 20 genes** (11 informative, 9 control and normalization) (13). A score ranging from 0 to 40 is generated by a multigene algorithm. It has been shown to correlate strongly with histologically diagnosed cellular allograft rejection. In the Cardiac Allograft Rejection Gene Expression Observational (CARGO) study, scores of < 34 were associated with a negative predictive value of > 99% for grade ≥3A/2R rejection. Several factors influence AlloMap score, including time posttransplantation, peripheral alloimmune activity, corticosteroid dose, and CMV. Transplant vasculopathy has been shown to be associated with increased AlloMap GEP score. GEP testing can be used in clinically stable cardiac transplant recipients who are > 15 years of age and 6 months or more posttransplantation. It is used to identify patients at low risk for moderate/severe (≥3A original ISHLT grade or ≥2R revised ISHLT grade) cellular rejection (8). In the Invasive Monitoring Attenuation through Gene Expression (IMAGE) trial, 602 patients who had undergone cardiac transplantation at least 6 months previously were randomly assigned to the AlloMap test or EMB. The composite primary outcome of the study was allograft dysfunction, death, or retransplantation. At 2 years, the cumulative rate of this composite end point was 14.5% with GEP and 15.3% with EMB. The AlloMap test was thus not inferior to EMB in detecting allograft rejection. However, wholesale embrace of the IMAGE trial is tempered by the limitations of the trial, including the enrolment of only 20% of potentially eligible patients and of patients at lower risk for rejection. The noninferiority margin chosen was wide and included events that would not be associated with rejection since not all cases of graft dysfunction, death, or retransplantation are due to rejection (14).

   The frequency of rejection surveillance using the GEP or AlloMap testing should be individualized to the patient's rejection history, immunosuppression regimen, time posttransplantation, and transplant center protocol. GEP is a cost-effective and less expensive alternative to EMB for monitoring allograft rejection in cardiac transplant patients. It has demonstrated great clinical promise in these early studies and may one day surpass EMB as the gold standard for rejection surveillance after cardiac transplantation.

4. **Cardiac magnetic resonance.** CMR is able to evaluate both the myocardial tissue composition, including edema and necrosis, and the allograft function, which makes it an attractive modality for assessing cardiac allograft rejection. Studies to date have, however, not demonstrated consistent results in human populations (15). Marie et al. (16) demonstrated a 97% negative predictive value and a 35% positive predictive value of elevated T2 relaxation times in a series of 123 scans in 68 heart transplant recipients, 82% of whom were within 1 year of transplantation. Relaxation time of at least 56 milliseconds measured with a black-blood sequence predicted moderate or greater biopsy-proven rejection with 89% sensitivity and 70% specificity, and treatment of rejection episodes resulted in normalized relaxation times. Subgroup analysis showed a correlation between positive results in conjunction with a negative biopsy and subsequent rejection episodes in the following 3 months (16). In another study, Taylor et al. (17) compared the performance of CMR with EMB in assessing acute cardiac allograft rejection in 50 patients, 802 ± 224 days posttransplantation. Acute rejection was confirmed by EMB in 11 cases and presumed in 8 cases with a recent fall in left ventricular ejection fraction (LVEF) not attributable to coronary allograft vasculopathy. CMR evaluated myocardial function, edema, and early and late post-gadolinium-DTPA contrast enhancement. With rejection defined as increased early contrast enhancement or myocardial edema, the sensitivity and specificity of CMR compared with EMB were 100% and 73%, respectively. Eight patients with presumed rejection had significantly elevated early myocardial contrast enhancement compared with controls, which reduced along with improvement in LVEF following increased immunosuppression. The drawback of CMR, however, is that it is expensive, time consuming, nonspecific, and not universally available. Moreover, it cannot be used in claustrophobic patients or those with significantly reduced renal function (i.e., those with acute kidney injury or chronic kidney disease with a glomerular filtration rate < 30 mL/min/1.73m^2) in whom the use of gadolinium has the attendant risk of nephrogenic systemic fibrosis.

A. Types of rejection

1. **Hyperacute rejection** is usually fatal and is the result of allograft rejection by preformed antibodies. It can occur immediately on surgical reperfusion. The incidence of hyperacute rejection is thankfully rare in the era of PRAs and prospective crossmatches.
2. **Cell-mediated rejection** is characterized by infiltration of mononuclear inflammatory cells that are predominantly T cells directed against the allograft. Variability in the interpretation of histologic grading of cellular rejection of EMB by pathologists led to the revision of the grading system in 2004 (11). Biopsy grades of ≥2R warrant accentuation of immunosuppression. If there is no hemodynamic compromise, then patients are routinely treated as outpatients with 100 mg of prednisone taken orally for 3 days. If there is a hemodynamic compromise or persistent or recurrent severe rejection (at least grade 2R), then many therapeutic options are available, including 1 g of intravenous Solu-Medrol for 3 days, conversion from cyclosporine to tacrolimus, OKT3, Atgam, Thymoglobulin, plasmapheresis, photopheresis, and total lymphoid irradiation (4).

Grade 0R: no acute cellular rejection.
Grade 1R: mild, low-grade, acute cellular rejection.
Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage.
Grade 2R: Moderate, intermediate-grade, acute cellular rejection.
Two or more foci of infiltrate with associated myocyte damage.
Grade 3R: Severe, high-grade, acute cellular rejection.

Diffuse infiltrate with multifocal myocyte damage ± edema ± hemorrhage ± vasculitis.

3. **Antibody-mediated rejection (AMR)** occurs due to preformed or de novo alloantibody (immunoglobulin G or M) against donor antigens. Such antibodies and complements are deposited in the donor coronary microvasculature and are demonstrable by immunofluorescence or by immunohistochemistry staining against CD68, C4d, or C3d complement fragments that mediate vascular injury and, ultimately, allograft failure. There has, however, been no consensus on its diagnosis. The ISHLT has recently proposed a framework for reporting AMR (18):

pAMR 0: negative for pathologic AMR.
Both histologic and immunopathologic studies are negative.
pAMR 1 (H+): histopathologic AMR alone.
Histologic findings are present and immunopathologic findings are negative.
pAMR1 (I+): immunopathologic AMR alone.
Histologic findings are negative and immunopathologic findings are positive.
pAMR 2: pathologic AMR.
Both histologic and immunopathologic findings are present.
pAMR 3: severe pathologic AMR.

This category recognizes the rare cases of severe AMR with histopathologic findings of interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis and/or karyorrhexis, and marked edema. The reported experience of the group was that these cases are associated with profound allograft dysfunction and poor clinical outcomes.

AMR is not routinely screened for in EMBs unless suspected clinically because of allograft dysfunction or hemodynamic compromise. Treatment options for patients with vascular rejection include intravenous or oral steroids, plasmapheresis, or immunoadsorption (4).

X. INFECTIOUS DISEASE AFTER TRANSPLANTATION. The risk of infection is highest in the first year post cardiac transplantation, accounting for 29% of deaths. Thereafter, the risk falls but remains > 10%. In the first month post transplantation, nosocomial infections predominate. The therapeutic immunosuppression consequent upon transplantation leaves cardiac allograft recipients vulnerable to opportunistic infections or reactivation of latent infection, particularly between 1 and 6 months. Infections after 6 months are usually community-acquired. An infectious disease specialist with an interest in transplantation is an invaluable resource to any transplant program. The two pathogens of particular interest in the transplant patient are CMV and pneumocystis jiroveci pneumonia (PJP), formerly called pneumocystis carinii pneumonia, but there are several potential pathogens including *Mycobacterium*, *Nocardia*, *Listeria*, *Candida*, *Aspergillus*, and *Strongyloides* (1,4).

A. Cytomegalovirus. Primary CMV infection occurs when a CMV-negative recipient receives a CMV-positive donor organ or is infected de novo from another source. Secondary CMV infection occurs when a CMV-positive recipient has reactivation of quiescent CMV infection with viremia after immunosuppression, particularly with induction therapy or bolus immunosuppression prescribed for a rejection episode. Active CMV disease may manifest as fevers, myalgias, gastritis, colitis, pneumonitis, retinitis, or leukopenia and thrombocytopenia. The most sensitive and specific test for diagnosing CMV is quantitative PCR. PCR detects CMV DNA in plasma and quantifies the CMV viral load. Although CMV DNA replication may be detected by PCR, most patients do not have the clinical syndrome of CMV disease. The issues of whether a detectable CMV viral load will progress to the clinical syndrome and whether to treat patients with CMV detection in the absence of symptoms remain controversial.

Prophylaxis against CMV disease is considered to be the standard of care for CMV-positive recipients (regardless of the CMV status of the donor) and CMV-negative patients with a CMV-positive donor. There is no consensus on the duration

of ganciclovir therapy in these patients. Most patients are initially treated with intravenous ganciclovir, followed by a variable course of oral valganciclovir or acyclovir. Periodic monitoring of the CMV viral load may assist in guiding the duration of therapy in these patients.

Passive immunization with CMV immunoglobulin (CytoGam) may be considered in patients deemed at risk for CMV disease, particularly if they have low levels of serum immunoglobulins (< 500 mg/dL). Patients undergoing induction therapy, polyclonal or monoclonal antibody therapy for steroid-resistant rejection, or increased immunosuppressive therapy for acute rejection should be deemed at risk for reactivation of CMV disease.

The duration of therapy with valganciclovir for active CMV disease is usually 3 to 6 weeks. An undetectable CMV viral load should be demonstrated in such patients before consideration is given for antiviral therapy discontinuation (4).

B. *Pneumocystis jiroveci* pneumonia. Transplant recipients are at increased risk for the development of PJP because of their immunocompromised state. PJP is rare if appropriate prophylaxis with trimethoprim–sulfamethoxazole (TMP–SMX) is provided. Patients intolerant to TMP–SMX may be treated with inhaled pentamidine or dapsone. PJP is rarely seen at maintenance immunosuppressant doses in transplant patients. TMP–SMX may be discontinued at 6 to 12 months after transplantation in most patients (4).

XI. CARDIAC ALLOGRAFT VASCULOPATHY (CAV).

CAV is a progressive, neointimal proliferative process in the epicardial coronary vasculature and in the microcirculation. It is common, with an incidence of 20%, 30%, and > 50% at 3, 5, and 10 years after transplantation. CAV is a significant cause of mortality beyond the first year after transplantation, accounting for 30% to 50% of deaths at 5 years. The pathophysiology of CAV is not completely understood. **Initially CAV was thought to be an accelerated form of atherosclerosis; however, it is now clear that both immunologic and nonimmunologic factors are involved in the process**. Chronic, subclinical, and immune-mediated injury at the level of the donor coronary endothelium creates a chronic inflammatory milieu. The exact mediator of the endothelial injury remains controversial, but it is probably multifactorial, including chronic humoral and cellular rejection, ischemic and reperfusion injury at the time of transplantation, and chronic CMV infection of endothelial cells. Table 13.10 lists risk factors for the development of CAV, of which older donor age and hyperlipidemia are well-established risk factors, whereas the others are potential risk factors.

Because donor hearts are denervated at explantation, **the transplant recipient typically will not experience cardiac angina from advanced CAV.** The clinical presentation of CAV previously unrecognized in a patient may include symptomatic or asymptomatic LV dysfunction, myocardial infarction, or cardiac arrhythmia, including ventricular arrhythmias, heart block, syncope, or sudden cardiac death. Owing to the usually asymptomatic nature of CAV, transplant recipients require frequent surveillance studies to detect significant vasculopathy, including coronary angiography with or without IVUS, cardiac perfusion magnetic resonance imaging, and dobutamine echocardiography. The frequency and method of surveillance are center-specific. Although coronary angiography is useful for the diagnosis of nontransplant coronary artery disease, its sensitivity is considerably less in CAV because of the diffuse nature of this disease. Coronary IVUS imaging provides useful tomographic perspective to study the development and progression of CAV and is now considered by many to be the gold standard modality for diagnosing CAV. However, not all centers have access to routine IVUS imaging and thus its use will vary greatly from center to center. The nomenclature of CAV has not been standardized until recently (19). The recommended nomenclature for CAV is as follows:

CAV0 (not significant): no detectable angiographic lesion.

ISHLT CAV1 (mild): angiographic left main (LM) < 50%, primary vessel with maximum lesion of < 70%, or any branch stenosis < 70% (including diffuse narrowing) without allograft dysfunction.

TABLE 13.10 Risk Factors for the Development of Cardiac Allograft Vasculopathy

Older donor age
Hyperlipidemia
Donor brain death secondary to spontaneous intracranial hemorrhage
Cytomegalovirus infection
Increased C-reactive protein levels (> 1.66 mg/L)
Recurrent cellular rejection
Humoral (vascular) rejection
HLA antigen mismatch
Donor hepatitis B and C
Female donor
Peritransplant myocardial ischemia
Pretransplant coronary atherosclerotic disease
Conventional atherosclerosis risk factors (diabetes, hypertension, and smoking)

HLA, human leukocyte antigen.

ISHLT CAV2 (moderate): angiographic LM < 50%, a single primary vessel ≥ 70%, or isolated branch stenosis ≥ 70% in branches of two systems, without allograft dysfunction.

ISHLT CAV3 (severe): angiographic LM ≥ 50%, two or more primary vessels ≥ 70% stenosis, or isolated branch stenosis ≥ 70% in all three systems; or ISHLT CAV1 or CAV2 with allograft dysfunction (defined as LVEF ≤ 45% usually in the presence of regional wall motion abnormalities) or evidence of significant restrictive physiology (which is common but not specific).

Definitions

(a) A "primary vessel" denotes the proximal and middle 33% of the left anterior descending artery, the left circumflex, the ramus, and the dominant or codominant right coronary artery with the posterior descending and posterolateral branches.

(b) A "secondary branch vessel" includes the distal 33% of the primary vessels or any segment within a large septal perforator, diagonals and obtuse marginal branches, or any portion of a nondominant right coronary artery.

(c) Restrictive cardiac allograft physiology is defined as symptomatic heart failure with echocardiographic E to A velocity ratio > 2 (> 1.5 in children), shortened isovolumetric relaxation time (< 60 milliseconds), shortened deceleration time (< 150 milliseconds), or restrictive hemodynamic values (right atrial pressure > 12 mm Hg, pulmonary capillary wedge pressure > 25 mm Hg, and cardiac index < 2 L/min/m^2).

The detection of significant CAV should prompt aggressive percutaneous or more rarely surgical revascularization. Because of its relationship with chronic rejection, advancement of the immunosuppressant regimen has also been advocated. Statins have been shown prospectively to decrease the incidence of transplant vasculopathy and improve survival, regardless of the patient's lipid profile (20). Preliminary studies investigating the antiproliferative effects of TOR inhibitors (sirolimus and everolimus) suggest a significant reduction in coronary neointimal proliferation and, therefore, transplant coronary vasculopathy. In the future, the development of transplant vasculopathy may prompt a switch to a TOR inhibitor–based immunosuppressant regimen if the initial suggestion of attenuation of progression, and perhaps regression, of transplant vasculopathy is confirmed in larger, prospective clinical trials. In severe, advanced CAV, frequently the only viable option is repeat transplantation (1,4).

XII. MALIGNANCY

A. Malignancy is a common and devastating complication of cardiac transplantation. In immunocompetent people, the cellular arm of the immune system actively defends against a variety of neoplastic processes. With the initiation of immunosuppression after transplantation, this defense mechanism is rendered feeble and previously undeclared neoplastic foci may proliferate. Because up to 38% of patients undergo cardiac transplantation for ischemic cardiomyopathy, a significant proportion of which is smoking-related, lung cancers can occur. Other common tumors include lymphomas, skin cancers, colon cancers, and breast cancers. Skin cancers are particularly common in patients on azathioprine, and they usually prompt a substitution of MMF for azathioprine. Posttransplantation malignancies are particularly common in patients who have received cytolytic or induction therapy with OKT3, Atgam, or Thymoglobulin, and the risk correlates with cumulative dosing of immunosuppression. The risk of developing a malignancy as a result of immunosuppression is enhanced by the inability to adequately assess for overimmunosuppression. Underimmunosuppression is readily detected because of the development of acute rejection, whereas there is no clinical finding to suggest overimmunosuppression.

PTLD is an Epstein-Barr virus–related clonal expansion of B lymphocytes. PTLD may develop in any location but most commonly affects the gastrointestinal tract, lungs, and central nervous system. The primary treatment for PTLD is a reduction in immunosuppression (by about 50%), which can frequently be curative. Surgical debulking, systemic chemotherapy, and antiviral therapy may also be indicated in selected patients (1,4).

XIII. HYPERTENSION

Arterial hypertension commonly develops after cardiac transplantation secondary to the untoward effects of immunosuppression. **Hypertension developing after cardiac transplantation occurs in most cyclosporine-treated and tacrolimus-treated patients**. Three mechanisms proposed are as follows:

(1) direct sympathetic activation,
(2) increased responsiveness to direct circulating neurohormones, and
(3) direct vascular effects.

A common end point of these proposed mechanisms is vasoconstriction of the renal vasculature, leading to sodium retention and an elevated plasma volume. Corticosteroids play a minor role in the pathogenesis of cardiac transplant hypertension, which is described as a salt-sensitive type. Abnormal cardiorenal reflexes secondary to cardiac denervation may also contribute to salt-sensitive hypertension and fluid retention.

Patients with blood pressure consistently > 140/90 mm Hg should be treated. Titrated monotherapy with either ACE inhibitors or calcium channel blockers is usually effective in about 50% of the patients. Some patients will be prone to hyperkalemia secondary to the combined effect of cyclosporine and ACE inhibition on the kidney. The use of diltiazem, verapamil, or amlodipine necessitates the use of lower doses of cyclosporine and initially more frequent cyclosporine level monitoring because these drugs are competitive antagonists of cyclosporine at the cytochrome P450 level. Combination therapy with both an ACE inhibitor and a calcium channel blocker is a commonly employed strategy. Problematic hypertensives requiring multiple agents often require diuretics as part of their regimen. Hypertension in some patients is inadequately controlled despite maximally tolerated doses of both calcium channel blockers and ACE inhibitors. The final tier of management would be to add a β-blocker such as clonidine or doxazosin in refractory cases. β-Blockers traditionally have been avoided due to their known tendency to reduce exercise performance and because of concerns about excessive bradycardia. Some transplant cardiologists, however, routinely use β-blockers to manage hypertension in their transplant patients. Thus, β-blockers are not contraindicated but rather may be used with due caution (1,4).

XIV. OUTCOMES AFTER CARDIAC TRANSPLANTATION. Survival outcomes after cardiac transplantation continue to improve on a yearly basis despite what is generally accepted as a population of transplant recipients at greater risk, primarily because of advancing recipient age and increasing severity of heart failure. The 1-year survival rate after cardiac transplantation is 84% nationwide, but it is frequently > 90% at large transplant centers. The mortality in the first year after transplantation primarily results from postoperative complications, including multiorgan failure, primary graft failure, and systemic infection. Those surviving the first year posttransplantation have a median survival of 13 years. It is unlikely that any major improvements in early posttransplant survival will occur in light of these excellent results. However, a 10-year survival rate after cardiac transplantation is only 50%. Mortality in the long term primarily results from transplant coronary vasculopathy, malignancy, and renal failure. It is hoped that a major impact can be made on long-term survival with newer immunosuppressive drug regimens that may be less nephrotoxic and more effective at preventing transplant coronary vasculopathy (1).

CHAPTER 14

Praneet Kumar
W.H. Wilson Tang

Pulmonary Hypertension

I. INTRODUCTION. Pulmonary hypertension (PH) is a routinely made diagnosis in contemporary cardiology and pulmonary clinics. It is essential for the specialist as well as the internist to have a high index of clinical suspicion for this devastating disease, as early diagnosis and referral may affect the survival. Substantial advances are being made in the management of pulmonary arterial hypertension (PAH), which is more rapidly available at centers specializing in PH.

A. Terminology/definitions. PH is defined as mean pulmonary artery pressure (mPAP) > 25 mm Hg. PH encompasses a heterogeneous group of diseases with a common clinical manifestation. The terms PH, which is a hemodynamic and pathophysiologic condition, and PAH, a clinical condition, are different terminologies that should not be used interchangeably. The clinical classification of PH is based on hemodynamic data derived from right heart catheterization (RHC). Some terminologies that are commonly employed in PH include the following:

1. **Trans-pulmonary gradient (TPG)** is defined as the pressure difference between mean left atrial pressure (LAP) (more commonly pulmonary capillary wedge pressure [PCWP] is used as a surrogate) and mPAP.
2. **Pulmonary vascular resistance (PVR)** is defined as TPG divided by the cardiac output (PVR = TPG/CO in Wood units).
3. **PAH** is hemodynamically defined as PH (i.e., mPAP ≥ 25 mm Hg) with increased PVR (more than 3 Wood units) and normal wedge pressure (< 15 mm Hg). It is a clinical condition characterized by precapillary PH and pathologic changes in the lung microcirculation.
4. **Pulmonary venous hypertension is characterized by mPAP ≥ 25 mm Hg, PVR > 3** Wood unit**, and elevated wedge pressure (PCWP ≥ 15 mm Hg).**

B. Classification. The World Health Organization has endorsed the clinical classification of PH based upon pathologic, pathophysiologic, and therapeutic characteristics. The most recent classification derived from the world symposium on PH held in Dana Point, California, in 2008 is listed in Table 14.1.

C. Epidemiology. The total PH burden of the disease is substantial as it represents an end stage of multiple disease processes such as left-sided heart disease, chronic lung diseases, as well as PAH which is very rare. Most of the patients who are diagnosed with PH on routine testing (echocardiogram with pulmonary arterial systolic pressure [PASP] > 40 mm Hg) will end up having left heart disease (nearly 80%), some with lung disease and hypoxia (10%), and only a small minority (4%) will have PAH.

Data from registries estimate the prevalence at around 15 to 50 cases/million adults and its incidence at around 2.4 cases/million adults/year. Idiopathic PAH (IPAH) and familial PAH (previously known as "primary PH") are rare diseases with a prevalence of around 6 cases/million. **Familial cases account for 5% to 10% of all PAH cases. Mutations in the *bone morphogenetic protein receptor-II* (BMPR2)**

TABLE 14.1 Dana Point Classification of Pulmonary Hypertension (Simplified)

	Type	Subtype
1	Pulmonary arterial hypertension	Idiopathic Heritable Drugs and toxins induced Associated with CTD, HIV, portal hypertension, congenital heart disease, schistosomiasis, and chronic hemolytic anemia Persistent PH of newborn
1′	Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis	
2	PH due to left heart disease	Systolic Diastolic Valvular
3	PH due to lung disease and/or hypoxia	COPD ILD Mixed obstructive and restrictive lung disease Sleep-disordered breathing Alveolar hypoventilation syndromes, etc.
4	Chronic thromboembolic PH	
5	PH with unclear and/or multifactorial mechanisms	Hematologic Systemic such as sarcoid and vasculitis

PH, pulmonary hypertension; CTD, connective tissue disease; HIV, human immunodeficiency virus; COPD, chronic obstructive pulmonary disease; ILD, interstitial lung disease.

gene have been identified in about 70% of patients with familial PAH and 10% to 40% of patients with sporadic IPAH. Hence, relatives of patients with familial IPAH should be advised about the availability of genetic testing and counseling in addition to echocardiographic screening.

PAH has been associated with environmental factors such as the use of drugs and toxins. **Anorexigens** (appetite suppressant drugs that increase serotonin release and block serotonin reuptake) have been associated with PAH, with agents such as aminorex fumarate and (dex) fenfluramine. Select patient populations at an increased risk of developing PAH are discussed below.

1. **Patients with connective tissue diseases** (CTDs), especially the **limited cutaneous form of systemic sclerosis (formerly referred to as the CREST syndrome)**. The prevalence of hemodynamically proven PAH in systemic sclerosis is around 10%. In other CTDs, such as systemic lupus erythematosus, mixed CTD, rheumatoid arthritis, dermatomyositis, and Sjögren's syndrome, PAH is observed less frequently.
2. **Human immunodeficiency virus (HIV) infection** is associated with approximately 0.5% incidence of PAH. However, because of this low incidence, routine screening is not recommended.
3. Patients with **cirrhosis and portal hypertension** are at an increased incidence of PH (5% of patients were referred for liver transplantation).

4. **Congenital heart disease** may lead to PAH when the underlying systemic-to-pulmonary shunt is not corrected. Most commonly, it occurs with conditions where blood flow is high and the pulmonary vasculature is exposed to systemic level pressures (e.g., ventricular septal defect and patent ductus arteriosus). However, high blood flow alone, as in atrial septal defect, may be sufficient. Once PVR approaches or exceeds the systemic vascular resistance, the shunt is reversed, leading to desaturation and cyanosis (Eisenmenger syndrome).

II. SIGNS AND SYMPTOMS

A. Symptoms. The symptoms of PH are nonspecific and are gradual in onset; therefore, there is a lag time of about 2 years (from symptom onset to diagnosis) in 90% of patients with PAH. These symptoms may include dyspnea on exertion, fatigue, weakness, chest pain, palpitations, syncope, abdominal distention, and pedal edema. Symptoms at rest occur only at late stages of the disease and portend poor prognosis.

Some patient populations are at an increased risk for developing PH and should be carefully screened by clinicians by careful history taking, examination, and laboratory tests. These populations include patients with known, or relatives of those with, BMPR2 mutations, CTD, HIV infection, portal hypertension, prior appetite suppressant use, congenital heart disease with shunt, recent acute pulmonary embolism, left heart disease, chronic obstructive pulmonary disease, interstitial lung disease, or sleep apnea.

It is advisable to perform annual screening with echocardiography in select high-risk groups, such as

(1) those with known BMPR2 mutation;
(2) first-degree relative of the patient with BMPR2 mutation or within pedigree of two or more patients with PAH;
(3) those with systemic sclerosis; and
(4) those with sickle cell disease.

B. Physical examination. Physical examination may provide clues as to the cause of PH. Findings of telangiectasia, digital ulceration, and sclerodactyly suggest scleroderma, while inspiratory crackles may point toward interstitial lung disease. Patients should be carefully screened for the presence of stigmata of liver disease, such as spider naevi, testicular atrophy, and palmar erythema. The presence of clubbing suggests congenital heart disease or pulmonary veno-occlusive disease. Cardiovascular examination of patients with PH may reveal a left parasternal lift, a loud P_2 at the apex, a pansystolic murmur of tricuspid regurgitation that increases with inspiration, a diastolic murmur of pulmonary insufficiency, and a right ventricular (RV) S_3. Lung sounds are usually normal (except for those with class 3 PH). Jugular vein distension, hepatomegaly with a pulsatile liver, peripheral edema, and ascites are ominous signs suggestive of advanced stages with right-sided heart failure.

III. LABORATORY EVALUATION

A. Blood work

1. Routine biochemistry, hematology, and thyroid function tests.
2. **Serologic testing** is important to detect the underlying CTDs, HIV (mandatory screening), thrombophilia (in chronic thromboembolic pulmonary hypertension [CTEPH]), and hepatitis (in patients with suspected liver disease). More than a third of patients with IPAH have low-titer elevation in antinuclear antibodies. Systemic sclerosis is the most important CTD to exclude because of high prevalence of PAH in this syndrome. Anti-centromere antibodies are usually positive in limited scleroderma as are other antinuclear antibodies, including dsDNA, anti-Ro, U3-RNP, B23, Th/To, and U1-RNP. In the diffuse variety of scleroderma, U3-RNP is positive. In patients with systemic lupus erythematosus, anticardiolipin antibodies may be found.

3. **Biomarkers.** Several circulating biomarkers have prognostic implications in patients with PAH, but their value in everyday clinical practice is still not established. Uric acid levels are shown to be increased in patients with IPAH, and elevated plasma troponin T levels (> 150 pg/mg) have been associated with worse outcomes in patients with CTEPH and PAH. BNP levels have also been used to monitor response to therapy or clinical course, as those with persistently elevated levels have worse outcomes. Similarly, NT-proBNP below cutoff levels < 1,400 pg/mL has been associated with better outcomes. BNP/NT-proBNP plasma levels should be checked for the initial risk stratification and may be considered for monitoring the effects of treatment, in view of their prognostic implications. Low and stable or decreasing BNP/NT-proBNP may be a marker of successful disease control in PAH.

B. The electrocardiogram (ECG). In typical cases of PH, the ECG shows right atrial (RA) dilatation, RV hypertrophy with strain, and a right axis deviation. In advanced stages of the disease, atrial flutter or atrial fibrillation often occurs, leading to further clinical deterioration.

C. Chest radiograph. Initial chest x-rays are abnormal in majority (90%) of patients with IPAH at the time of diagnosis. There is often central pulmonary arterial (PA) dilatation with "pruning" (loss) of the peripheral blood vessels, clear lung fields, and a prominent RV border. The chest x-ray may also point to lung abnormalities and show features suggestive of left heart disease.

D. Echocardiography. If PH is suspected based on history, risk factor assessment, and physical examination, an echocardiogram is the next appropriate study. By using the Doppler technique, peak velocity of the tricuspid regurgitation jet can be measured. From this measured velocity, the pressure difference between right ventricle and right atrium can be estimated by employing the simplified Bernoulli equation ($\Delta P = 4v^2$). On condition that there is no pulmonic valve stenosis, PASP = 4 × (tricuspid regurgitant jet velocity)^2 + right atrial pressure (RAP). RAP can be estimated on the basis of inferior vena cava (IVC) characteristics. If the IVC is plethoric and there is clinical evidence of Jugular venous distension (JVD), RAP is presumed to be 10 to15 mm Hg, whereas if findings are normal, it is usually calculated as 5 mm Hg.

Other echocardiographic characteristics may raise the suspicion of PH, such as RA or RV dilatation, flattening of the interventricular septum with D-shaped left ventricle, increased RV wall thickness, dilatation of the pulmonary artery, and the presence of pericardial effusion. These features tend to occur later in the course of the disease.

Although echocardiography is a useful screening tool, Doppler-derived pressure estimation can both underestimate PASP in patients with severe tricuspid regurgitation and overestimate PASP in non-PH patients. Ultimate confirmation requires RHC.

E. Right heart catheterization. RHC is required to ***confirm the diagnosis of PH, to assess the etiology and severity, and to test for vasoreactivity of the pulmonary circulation***. At experienced centers, morbidity (1.1%) and mortality (0.055%) rates are low. Consecutively, RAP, right ventricular pressure (RVP), PAP, and PCWP are recorded using a balloon-tipped fluid-filled catheter (Table 14.2). Cardiac output can be determined using the thermodilution method and/or the Fick method (measurement of mixed venous saturation SvO_2 needed). The PCWP is taken as a surrogate measure of LAP and, in the absence of mitral stenosis, left ventricular end-diastolic pressure (LVEDP). This measurement is very important because it helps differentiate PH associated with left heart disease from other conditions. However, it is subject to error in measurement and interpretation. Occasionally, it may be necessary to perform a left heart catheterization for direct measurement of LVEDP.

TABLE 14.2 Normal Values of Pressures and Measurements Derived from a Right Heart Catheterization

Measured characteristic	Normal value
Right atrial pressure	Mean 1–10 mm Hg
RVSP/RVDP	15–30/1–10 mm Hg
PASP/PADP	15–30/5–10 mm Hg (mean < 20 mm Hg)
PCWP	Mean 5–12 mm Hg
LVEDP	5–12 mm Hg
Cardiac output Cardiac index	5–7.5 L/min 2.5–4.0 L/min/m^2
PVR	0.25–1.6 Wood units
TPG	4–6 mm Hg

RVSP/RVDP, right ventricular systolic and diastolic pressures; PASP/PADP, pulmonary artery systolic and diastolic pressures; PCWP, pulmonary capillary wedge pressure; LVEDP, left ventricular end-diastolic pressure; PVR, pulmonary vascular resistance; TPG, transpulmonary gradient.

Temporal evolution of the hemodynamic variables with progression of PAH is depicted in Figure 14.1. As the disease progresses, the right ventricle starts to fail, leading to reduction in CO. As a result, PAP may decrease again. This decrease may give a false impression of hemodynamic improvement or suggest that there is mild to moderate disease. Therefore, it is imperative to measure PVR, which will be high in this situation. Usually, the RAP and PCWP also increase, implying RV failure and left ventricular (LV) diastolic dysfunction, respectively. The latter is the consequence of ventricular interdependence and abnormal compliance of the left ventricle produced by an enlarged right ventricle.

Vasoreactivity testing in PAH: In PAH, vasoreactivity testing should be performed to identify patients who may benefit from long-term therapy with calcium channel blockers

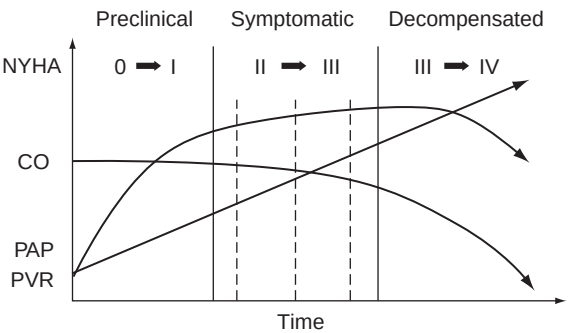

FIGURE 14.1 Evolution of hemodynamic variables in function of disease severity. CO, cardiac output; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance. (From Galie N, Manes A, Palazzi M, et al. Pharmacological impact on right ventricular remodelling in pulmonary arterial hypertension. *Eur Heart J.* 2007; 9:H68-H74, with permission.)

(CCBs). The agent most often used to test this is inhaled NO, with (i.v.) epoprostenol and (i.v.) adenosine as alternatives.

A positive acute response is defined as a > 10 mm Hg decrease in mPAP to reach an absolute value of mPAP < 40 mm Hg with an increased or unchanged CO and without significant drop in systemic blood pressure.

In patients with IPAH, about 10% to15% are acute responders and nearly half of these will prove to be long-term responders with a more favorable prognosis. This concept is less clear in other forms of PAH, although vasoreactivity testing is still recommended but controversial in congenital heart disease. It is not useful in other forms of PH (groups 1', 2, 3, 4, and 5). In veno-occlusive disease and left heart disease, it can even provoke pulmonary edema. However, in patients considered for heart transplantation, pulmonary vasoreactivity testing may be used to assess reversibility and operability.

It is important to understand the difference between PAH vasoreactivity testing and the assessment of PH reversibility in left-sided heart failure. In PAH, vasodilator response testing is performed to select patients who may respond favorably to CCBs as the first agent versus those who will likely not. In left-sided heart failure and PH, vasodilatory drugs that affect the LV afterload, such as sodium nitroprusside, are given with an intention to reduce LV filling pressure and, evaluate for reversible pulmonary hypertension. Those who have persistent elevation in TPG and PVR to high levels (such as when TPG remains elevated to > 15 mm Hg and/or PVR is > 3 Wood units despite the reduction of PCWP to < 15 mm Hg) are at high risk for transplant failure, as the transplanted heart may not withstand persistently elevated PAPs , which results in right heart failure.

F. Pulmonary testing and arterial blood gas (ABG). Pulmonary function tests and ABGs are used to identify underlying airway or parenchymal lung disease. Patients with PAH usually have decreased lung diffusion capacity for carbon monoxide (typically in the range of 40% to 80% predicted) and mild to moderate reduction in lung volumes. Arterial oxygen partial pressure is normal or only slightly lower than normal at rest and arterial carbon dioxide partial pressure is decreased because of alveolar hyperventilation. The severity of emphysema and of interstitial lung disease can be diagnosed using high-resolution computed tomography (CT). If clinically suspected, screening overnight polysomnography may diagnose significant obstructive sleep apnea.

G. Six-minute walk distance. The 6-minute walk test (6MWT) is the most commonly employed measure of exercise capacity in patients with PH, both in clinical assessment and in research settings. In addition to the distance walked, the degree of dyspnea (Borg score) and oxygen saturation are also measured. **A 6-minute walk distance of < 332 m and a drop in oxygen saturation by > 10% are suggestive of poor prognosis**. It is also measured on routine follow-ups and can be indicative of clinical deterioration. It may also be used to assess the response to therapy.

H. Other tests. Chest CT and ventilation–perfusion (V/Q) scans are indicated to exclude primary parenchymal or thromboembolic diseases as a cause of PH. For excluding thromboembolic disease, V/Q scan is the preferred screening test. A normal or low-probability V/Q scan effectively excludes CTEPH with a sensitivity of 90% to 100% and a specificity of 94% to 100%, while a high-probability scan warrants further evaluation with a pulmonary angiogram. Pulmonary angioscopy may be considered at specialized centers in cases of CTEPH to determine surgical candidacy.

IV. PATHOGENESIS

A. Hemodynamically, PH is a disease state with increased pulmonary pressures. Applying Ohm's law to the pulmonary circulation

TPG or pressure difference (mPAP – PCWP) = flow (CO) × resistance (PVR).

Thus, elevated mPAP may be a consequence of ***elevation in PCWP, increase in flow, or increase in PVR***. However, pulmonary vessels are highly compliant and capable of recruitment with progressive reduction in PVR for the increment in flow. These low-pressure, low-resistance, and high-compliance characteristics of the pulmonary vascular bed are regulated by a balance between vasodilators and vasoconstrictors and between cell proliferation and apoptosis. Genetic and environmental factors may disturb this balance, resulting in excessive vasoconstriction, vascular remodeling, and micro-thrombosis, which leads to pulmonary (arterial) hypertension. This leads to elevated PVR and an increase in RV afterload, ultimately resulting in RV dilatation and hypertrophy. This may progress to RV failure with further dilatation, thinning of the wall and tricuspid regurgitation, and worsening outcome.

B. Histologically, PAH is a panvasculopathy predominantly affecting the small pulmonary arteries. The initial lesions seem to be intimal hyperplasia and medial hypertrophy followed by more irreversible lesions such as intimal fibrosis, thrombosis in situ, inflammation, and plexiform arteriopathy. These lesions may be present in various distributions, local or diffuse, in a patient.

C. Molecular and endothelial abnormalities. Various vasoactive molecules play an important role in the pathologic evolution of PAH. Our understanding of these factors and various pathologic forces is limited, but some pathways have been elucidated mainly due to their therapeutic potential (Fig. 14.2).

1. **Prostacyclin/thromboxane A_2:** Prostacyclin and thromboxane A_2 are arachidonic acid metabolites in vascular cells. Prostacyclin has potent vasodilating, antiproliferative, and platelet-inhibiting properties, whereas thromboxane A_2 has the opposite effect. In PAH, the balance is shifted toward thromboxane A_2 in small and medium-sized pulmonary arteries.
2. **Endothelin-1 (ET-1):** ET-1 is produced by endothelial cells and exerts its effect on the smooth muscle cells through two receptors: endothelin receptor A (ET_A), expressed on vascular smooth muscle cells, and endothelin receptor B (ET_B), expressed on both vascular endothelial cells and smooth muscle cells. Stimulation of both receptors on the vascular smooth muscle cells causes vasoconstriction and has a mitogenic effect, whereas stimulation of ET_B on the endothelial cells causes vasodilatation via increased production of prostacyclin and nitric oxide (NO). In patients with PH, ET-1 levels are increased and ET-A receptors are abundant.
3. **Nitric Oxide:** NO is produced in endothelial and epithelial cells in the lung from L-arginine by three isoforms of NO synthases (NOSs). It is a potent vasodilator and an inhibitor of platelet activation and of vascular smooth muscle cell proliferation. Once formed, the effects of NO are mediated by cyclic guanosine monophosphate (cGMP), which is rapidly inactivated by the phosphodiesterase enzymes, especially type 5 (PDE-5). Decreased endothelial NOS (NOS 3) has been observed in patients with PAH.
4. **Others:** Various molecules such as serotonin, vasoactive intestinal peptide, and angiopoietin-1, and various inflammatory cells have been associated with PAH.

V. TREATMENT. The treatment of group 1 PH (or PAH) is primarily in the form of pulmonary-specific vasodilator therapy, whereas treatment in groups 2, 3, and 4 PH is mainly oriented toward treating the underlying condition (such as left heart disease and chronic lung disease).

A. General measures. A few general measures apply to all the PH groups:

(1) Mild physical activity, possibly via exercise rehabilitation, is beneficial.

(2) Routine influenza and pneumococcal vaccinations are recommended.

(3) Contraception should be discussed with females of child-bearing age, as pregnancy carries a 30% to 50% mortality risk and is contraindicated.

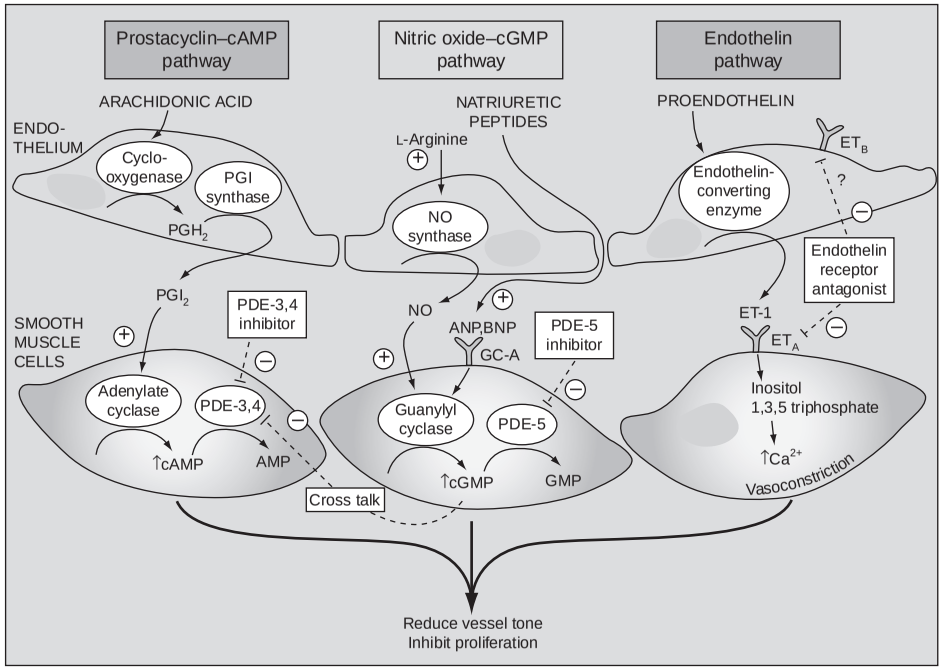

FIGURE 14.2 Therapeutic targets in pulmonary hypertension. cAMP, cyclin adenosine monophosphate; cGMP, cyclin guanosine monophosphate; PGI_2, prostacyclin; PGH_2, prostaglandin H_2; PDE, phosphodiesterase; NO, nitric oxide; ET, endothelin. (Reprinted from Benza RL, Park MH, Keogh A, et al. Management of pulmonary arterial hypertension with a focus on combination therapies. *J Heart Lung Transplant*. 2007;26(5):437–446, with permission from Elsevier.)

(4) Oxygen supplementation is advised to maintain saturation above 90%.
(5) Exposure to high altitude should be avoided. If flying, supplemental oxygen should be used if the patient's preflight saturation is less than 92%.
(6) Diuretic therapy is indicated to manage RV failure with volume overload.
(7) Digoxin may be considered in the case of atrial tachyarrhythmias.
(8) Oral anticoagulation is recommended in CTEPH, in IPAH, and in advanced diseases (e.g., continuous i.v. therapy). In PAH, a low therapeutic value of international normalized ratio (between 1.5 and 2) is generally targeted; however, this has not been evaluated in a randomized controlled trial (RCT).

B. Pulmonary vasodilators. The initial treatment choice in PAH is guided by vasoreactivity testing. For the responders (about 10% to 15% of the IPAH population), CCBs are the first line of treatment. Careful reassessment for safety and efficacy is mandatory, because only half of these patients will prove to be long-term responders and many will need additional vasodilators. The current treatment algorithm for PAH as suggested by the 2009 ACCF/AHA expert consensus document is shown in Figure 14.3.

1. **Prostacyclin analogs:** Prostacyclin is a potent endogenous vasodilator and an inhibitor of platelet aggregation and also appears to have antiproliferative activity. This may explain why *epoprostenol* (Flolan) can be used to acutely lower PAPs (as used in vasoreactivity testing) as well as to achieve long-term hemodynamic improvement in patients with PH who are nonresponders. In RCTs, epoprostenol has been shown to improve the functional class, exercise tolerance, hemodynamics, and survival in patients with IPAH. Epoprostenol has to be administered in a continuous i.v. infusion, and early titration often results in unbearable side effects of nausea, headache, flushing, jaw and leg pain, and diarrhea. Adverse events related to the delivery system include pump malfunction, local site infection, catheter obstruction, and sepsis. *Treprostinil* (Remodulin) is another prostacyclin analog that can be administered by inhalation, orally, or via continuous subcutaneous pump. It has been shown to improve the exercise

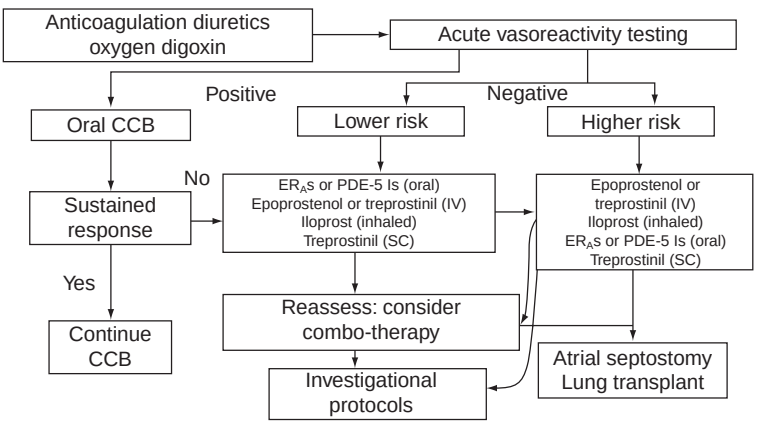

FIGURE 14.3 PAH treatment algorithm. CCB, calcium channel blocker; ERA, endothelin receptor antagonist; PDE-5 Is, phosphodiesterase type 5 inhibitors. (Reprinted from McLaughlin VV, Archer SL, Badesch DB, et al. ACCF/AHA 2009 Expert Consensus Document on Pulmonary Hypertension. *J Am Coll Cardiol*. 2009;53(17):1573–619, with permission from Elsevier.)

capacity, hemodynamics, and symptoms. Infusion site pain is the most common side effect. *Iloprost* (Ventavis) is available as an aerosol administration and has a proven beneficial effect in patients with PAH and CTEPH.

2. **Endothelin receptor antagonists (ERAs):** *Bosentan* (Tracleer) is an oral active dual ET_A/ET_B receptor antagonist that has been shown to improve the exercise capacity, functional class, hemodynamics, and cardiac performance as measured by echocardiography and clinical outcomes. *Sitaxsentan* and *ambrisentan* are more selective ET_A receptor antagonists with similar benefits as bosentan. Liver injury and teratogenicity are major concerns and require monthly monitoring.
3. **PDE-5 inhibitors:** Orally active PDE-5 inhibitors prevent the degradation of cGMP, causing vasorelaxation. *Sildenafil* (Revatio) has favorable effects on exercise capacity, symptoms, and hemodynamics. Tadalafil (Adcirca) has the same effects, although it also delays the time to clinical worsening. Headache, flushing, dyspepsia, and epistaxis are the usual side effects.

In low-risk patients, oral therapy with ET receptor antagonists or PDE-5 inhibitors is the first choice, whereas i.v. epoprostenol is reserved for the high-risk population. Combination therapy is being routinely employed if treatment goals are not achieved with one compound ("goal-directed therapy"). The rationale is based on attacking different pathologic processes with different agents.

C. Treatment of non-group 1 PAH. Many pulmonary vasodilators have been evaluated for various non-PAH groups such as left-sided heart disease and lung disease. The following recommendations are based on current evidence:

1. **Group 2 PH (left-sided heart disease):** prostanoids and ERAs are associated with an increased event rate in patients with LV dysfunction and are contraindicated. There is some evidence of improvement in the quality of life, exercise performance, and hemodynamics with sildenafil in patients with left heart disease and in patients bridged to transplantation with a left ventricular assist device.
2. **Group 3 PH (lung disease of hypoxia):** pulmonary vasodilators are not recommended.
3. **Group 4 PH (CTEPH):** prostanoids, ERAs, or PDE-5 inhibitors may be used prior to surgery to improve hemodynamics. It may be used in patients with predominant peripheral disease or in those with persistent PH after surgery.

D. Surgical therapies. In CTEPH, surgery (pulmonary endarterectomy) is potentially curative in patients with accessible (proximal) disease. It is recommended that surgical evaluation and procedure be performed at high volume centers. Balloon atrial septostomy is rarely performed for palliation in patients with advanced PAH with recurrent syncope and/or right heart failure who have failed all available medical treatments. RV assist devices have emerged as a therapy in postoperative RV failure in the presence of PH. Heart–lung transplantation should be considered in a subset of eligible patients who remain in New York Heart Association functional class III or IV or in those who cannot achieve a significant exercise and hemodynamic improvement after 3 months of epoprostenol therapy.

VI. CONTROVERSIES.

Several controversies exist in the clinical and research arenas regarding PH, leading to frequent difference of opinions among referring internists, pulmonologists, and cardiologists. It is therefore important to identify such areas of concern. This may help target future research and identify these patients who would benefit from management at a specialized center where a multidisciplinary approach may be provided.

A. Most therapies (except epoprostenol) in PAH have not shown mortality benefits. Most therapeutic trials are small randomized clinical trials with soft end points such as 6MWT, exercise tolerance, and improvement in dyspnea scoring. While this raises

valid concerns regarding the long-term benefit of many expensive drugs, it is interesting that the overall survival in this patient population is improving.

B. Pulmonary vasodilators have generally been ineffective or harmful in patients with left-sided heart failure. However, PDE-5 inhibitors are an exception, as there have been multiple small studies that suggest improvement in exercise parameters and hemodynamics. One study, PhosphodiesteRasE-5 Inhibition to Improve CLinical Status And EXercise Capacity in Diastolic Heart Failure Study (RELAX), is currently enrolling participants to study the effect of sildenafil in patients with diastolic heart failure.

C. In "out-of-proportion" PH, many patients with left-sided heart failure may have only modest increase in PCWP (< 22 to 25 mm Hg) but very high PAP (systolic PAP > 60 mm Hg) with high TPG (> 18 mm Hg). This usually happens in patients who have developed a "fixed" PH, as opposed to a very few who have both left-sided heart failure and PAH.

D. Pulmonary vasoreactivity is often used in heart transplant candidates with "out-of-proportion" PH by administering sodium nitroprusside or nitroglycerin in the cardiac catheterization laboratory and assessing hemodynamics with reduction in PCWP. Those who have reduction in PAP and TPG may be able to undergo transplantation without right heart failure.

E. The treatment for "out-of-proportion" PH is primarily focused on treating the underlying left-sided failure.

VII. PROGNOSIS AND FOLLOW-UP

A. Prognosis. Survival in patients with PH differs between PH groups and also within each group depending on the etiology. For example, the prognosis in patients with severe aortic stenosis with PH will be different from that of patients with diastolic heart failure and PH. Similarly, it is quite different between idiopathic and scleroderma-related PH. Evaluating disease severity and predicting survival is important because it may guide clinical management. Best data regarding prognosis are available for the IPAH subset population. The natural history of this group shows survival rates of 68%, 48%, and 34% after 1, 3, and 5 years, respectively. There is registry level evidence that prognosis has improved with pulmonary vasodilator therapies. Table 14.3 outlines clinical, echocardiographic, and hemodynamic features that may

TABLE 14.3 Prognostic Variables in Pulmonary Hypertension

Lower	Determinants of risk	Higher
No	Clinical evidence of RV failure	Yes
Gradual	Progression	Rapid
II, III	WHO class	IV
Longer (> 400 m)	6-Min walk distance	Shorter (< 300 m)
Minimally elevated	BNP	Very elevated
Minimal RV dysfunction	Echocardiographic findings	Pericardial effusion Significant RV dysfunction
Normal/near-normal RAP and CI	Hemodynamics	High RAP, low CI

RV, right ventricular; BNP, brain natriuretic peptide; RAP, right atrial pressure; CI, cardiac index.

Adapted from McLaughlin VV, Presberg KW, Doyle RL, et al. Prognosis of pulmonary arterial hypertension*: ACCP evidence-based clinical practice guidelines *Chest*. 2004;126:78s–92s.

predict the prognosis in patients with PAH. Again, these data are mainly derived from the IPAH population, and it is unknown whether these data are transferable to other P(A)H populations.

B. Follow-up

1. **Frequency**: Longitudinal follow-up of patients with PAH should be done at a center that specializes in PAH management with a sizeable patient population. Such centers have nurses, physicians, and ancillary support who are experienced in managing the disease and its complications. The frequency of follow-up depends on the clinical course. Those who have stable clinical course (i.e., with no evidence of heart failure, normal RV size/function, functional class I–II, 6MWT > 400 m, normal/near-normal hemodynamics, and stable BNP levels, and those maintained on oral therapy) should have clinical visits every 3 to 6 months. Unstable patients—those with sign of right heart failure, 6MWT < 300 m, abnormal hemodynamics, increasing BNP, and on i.v. therapy or combination therapy—should be evaluated every 1 to 3 months.
2. **Routine evaluation:** Assessment at each visit should include physical examination, assessment of functional class, 6MWT at each visit, and echocardiogram at 6 to 12 months, and blood work including biomarkers are usually performed at each visit or with change in clinical status or therapy; RHC is performed every 6 to 12 months in unstable patients and in stable patients it is performed when there is clinical deterioration or change in therapy.

SECTION III

Valvular Heart Disease

EDITOR

Brian P. Griffin

CHAPTER 15

Olcay Aksoy
Brian P. Griffin

Aortic Valve Disease

I. AORTIC STENOSIS

A. Introduction. Aortic stenosis (AS) causes progressive obstruction of the left ventricular outflow tract (LVOT), resulting in pressure hypertrophy of the left ventricle and the classic symptoms of heart failure, syncope, and angina pectoris. Stenosis most commonly occurs at the level of the valve (AS); however, subaortic and supravalvular stenoses are also well-defined entities. Untreated AS is associated with significant morbidity and mortality. As prompt recognition and treatment are associated with normalized life expectancy in those patients with symptomatic severe AS, careful evaluation and management can have significant impact on survival.

B. Etiology

1. Valvular AS has several causes, including congenital, rheumatic, bicuspid, and most commonly inflammation with resultant calcification.

a. The most common cause of AS in the United States is calcific degeneration. Although initially thought to be the result of normal "wear and tear" of the valve leaflets, there is now ample evidence that suggests that the progression of stenosis is related to an active process of inflammation involving the renin–angiotensin system, lipid accumulation, and resultant calcification. Several inflammatory pathways are implicated, including those that utilize osteopontin, bone morphogetic proteins, and receptor activator of nuclear factor-κB ligand.

Aortic sclerosis is caused by calcification and thickening of the aortic valve without the increased gradients as seen in AS. Both aortic sclerosis and calcific aortic stenosis have been associated with traditional risk factors for atherosclerosis, such as smoking, hypertension, and hyperlipidemia. Aortic sclerosis is associated with an increased risk of cardiovascular death and myocardial infarction and can progress to AS. Other conditions associated with calcific AS include Paget's disease and end-stage renal disease.

b. Bicuspid valves are present in 1% to 2% of the population, are predominant in men, and occur in **9% of first-degree family members** of those afflicted. The most common anatomic abnormality seen in a bicuspid valve is the fusion of the right and left coronary cusps. Concurrent **coarctation, aortic root dilation, and a propensity for aortic dissection are seen** in a minority of patients. Severe stenosis typically develops by the fifth or sixth decade; however, earlier and later presentations are not uncommon. Unicuspid valves open only at one commissure, are uncommon, and are usually severely stenotic at an early age.

The most recent American College of Cardiology/American Heart Association (ACC/AHA) valve guidelines (2006) highlight the importance of evaluating the aorta and valve in bicuspid aortic valve with echocardiography or, if this is inadequate, with other imaging modalities such as magnetic resonance imaging or computed tomography. In some instances, the aorta may require surgical intervention before the valve. The guidelines recommend that patients with an aortic diameter > 4 cm and bicuspid valve should have

yearly follow-up of aorta size and should have **surgical intervention if the aorta is > 5 cm or increases by > 0.5 cm in a year**, irrespective of the valve lesion severity. **If the valve requires surgery, then aorta replacement is recommended if the aorta is > 4.5 cm at the time of surgery**. β-Blockers should be considered in bicuspid aortic valve patients in the presence of ascending aorta enlargement.

c. **Rheumatic AS** often coexists with aortic regurgitation (AR) and mitral valve lesions. It is a rare cause of isolated severe AS in the industrialized world. Fusion of the commissures occurs leaving a small central orifice.

2. **Subvalvular AS.** This is a congenital condition, although it may not be apparent at birth. Typically, a circumferential **fibromuscular membrane involving the anterior mitral valve leaflet is present in the LVOT below the aortic valve.** In more extreme cases, a tunnel-like obstruction may be present, rather than a discrete membrane. The pathogenesis of this condition is not perfectly understood but is thought to represent a maladaptive response to abnormal flow dynamics in the LVOT. It may exist with other left-sided obstructive lesions, such as coarctation as part of Shone's syndrome. The condition may recur even after successful membrane resection. Subvalvular AS may be difficult to distinguish from hypertrophic cardiomyopathy, especially when secondary left ventricular hypertrophy (LVH) is pronounced.
3. **Supravalvular AS** is uncommon. It may occur as part of a congenital syndrome such as Williams syndrome caused by a mutation in the elastin gene (i.e., associated hypercalcemia, elfin facies, developmental delay, small stature, and multiple stenoses in the aorta and peripheral arteries) or be caused by lipid deposits in severe forms of familial hypercholesterolemia. Obstruction occurs above the valve in the ascending aorta.

C. Pathophysiology

1. **Pressure overload.** All forms of AS are characterized by progressive narrowing of the LVOT. To maintain cardiac output in the face of increased afterload, the left ventricle must generate higher systolic pressures, which increases LV wall stress. In response to the pressure overload and increased wall stress, the left ventricle undergoes compensatory, concentric hypertrophy. The increase in LV wall thickness allows the wall stress to normalize according to Laplace's law: wall stress = (pressure × radius)/(2 × thickness).
2. **Diastolic dysfunction.** LV diastolic function is determined by LV relaxation properties and LV compliance (i.e., change in volume with change in pressure [dV/dP]). Increased afterload and LVH lead to a reduction in LV compliance. Furthermore, there are changes in strain and torsion characteristics of the left ventricle in AS. Passive early diastolic filling is reduced, and maintenance of an adequate LV preload becomes more dependent on active left atrial contraction.
3. **Supply–demand mismatch.** Myocardial oxygen demand is determined by heart rate, cardiac contractility, and myocardial wall stress. Over time, LVH is unable to compensate for the increase in wall stress imposed on the left ventricle by progressive pressure overload. As the AS becomes more severe, wall stress and myocardial oxygen demand increase in parallel. Concurrently, AS is associated with a decrease in myocardial oxygen supply. Progressive LVH and diastolic dysfunction lead to an elevation in left ventricular end-diastolic pressure (LVEDP). Elevated LVEDP leads to decreased perfusion pressure across the coronary bed and causes endocardial compression of small intramyocardial arteries, impairing coronary flow reserve. The imbalance between myocardial oxygen supply and demand can precipitate ischemia during exertion.

D. Natural history. The classic survival curve for patients with untreated AS, as described by Ross and Braunwald (1), is shown in Figure 15.1.

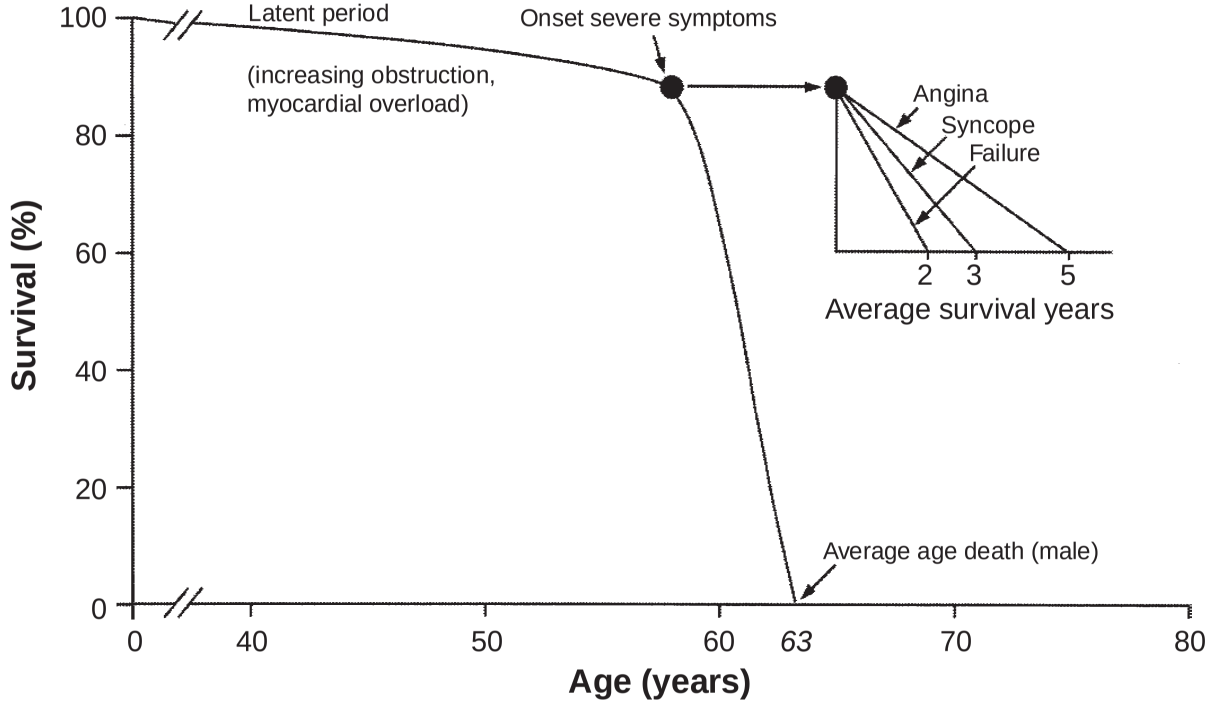

FIGURE 15.1 Patient survival in aortic stenosis.

1. **Asymptomatic patients**
   a. The disease process of AS is characterized by a long latent phase, during which the patient has no symptoms. This period is associated with near-normal survival. The risk of sudden cardiac death in asymptomatic patients with critical AS is < 2% per year.
   b. Although the underlying cause helps predict the age of symptom onset, there is marked individual variability in the length of the latent period and the subsequent rate of progression of disease. In general, among asymptomatic valvular AS patients, the mean aortic valve gradient rises by 7 mm Hg/y and the aortic valve area (AVA) decreases by 0.1 cm^2/y.
   c. Because of the variable rate of disease progression, all patients with AS should be advised to report the onset of any symptoms to their physician and should be followed clinically and with Doppler echocardiography with increasing frequency as the lesion progresses.
   d. Once the **valve becomes severely narrow**, as evidenced by a peak **Doppler velocity of 4 m/s across it, the likelihood of developing symptoms or requiring surgical intervention over the following 2 years is very high.** This likelihood is increased if the valve is heavily calcified.
2. **Symptomatic patients.** When symptoms of AS develop, the survival rate decreases markedly, unless aortic valve replacement (AVR) is performed.
   a. Patients with **angina** have a 50%, 5-year survival rate without surgical intervention. Those with **syncope** have a 50%, 3-year survival rate without surgical intervention. Patients with **heart failure** have a mean survival time of < 2 years if treated medically.
   b. In patients with severe, symptomatic AS, sudden cardiac death can occur in the setting of hypotension or arrhythmia due to ischemia, LVH, or impaired LV function.
   c. Signs and symptoms of severe AS might be subtle in some patients. Information concerning activity levels from family members may be useful in this situation, as may a symptom-limited stress echocardiogram. Exercise stress testing is absolutely contraindicated in the setting of definite symptoms.

E. **Clinical manifestations**
1. **Signs and symptoms.** The onset of symptoms usually indicates progression to severe AS and heralds the need for surgical evaluation.
   a. **Angina.** Patients with severe AS can experience ischemia from myocardial supply–demand mismatch due to high LV diastolic pressures, decreased myocardial perfusion, and increased wall stress. Angina can also result from underlying coronary artery disease (CAD). CAD is common among patients with severe AS. It occurs in 40% to 80% of patients with angina and in 25% of patients without angina.
   b. **Syncope.** Because of fixed LVOT obstruction, patients with severe AS are unable to augment their cardiac output under conditions of low systemic vascular resistance (SVR) (i.e., induced by certain medications or vasovagal reactions). The ensuing hypotension can cause presyncope, syncope, or even cardiovascular collapse and death. Syncope can also result from atrial or ventricular arrhythmias, abnormal baroreceptor function, or abnormal vasodepressor responses induced by LV pressure overload.
   c. **Heart failure** symptoms, such as exertional dyspnea, orthopnea, or paroxysmal nocturnal dyspnea, and fatigue can result from LV systolic or diastolic dysfunction.
2. **Physical findings**
   a. **Arterial examination.** A hallmark finding in AS is a diminished and delayed carotid upstroke, pulsus parvus et tardus. However, elderly patients

with noncompliant vessels or patients with concomitant AR may often maintain a normal carotid pulsation, despite severe AS. These findings are rare with obstruction above or below the valve. It is classically thought that severe AS is not associated with hypertension, as the narrowed valve limits the flow into the arterial system and thus gives rise to a narrowed pulse pressure and relative hypotension. In fact, in the elderly, hypertension and severe AS may often coexist, likely as a result of impaired elasticity of the aortic walls, and the finding of arterial hypertension does not preclude significant associated AS.

b. Palpation. With LVH and normal LV cavity dimensions, the apical impulse is usually nondisplaced, diffuse, and sustained. However, the apical impulse may later be displaced when there is LV systolic dysfunction. A double apical impulse represents a palpable *a* wave or S_4, caused by a noncompliant left ventricle. A systolic thrill may be palpable in the second right intercostal space.

c. Auscultation. The main auscultatory findings are shown in Figure 15.2.

(1) The typical murmur of AS is a systolic ejection murmur heard at the right upper sternal border that radiates to the neck. With a mobile bicuspid valve, an aortic opening sound may precede the murmur. As the severity of stenosis increases, the murmur becomes longer and peaks later in systole. The intensity of the murmur does not necessarily correspond to the severity of AS. S_1 is usually normal in AS. As the AS becomes more severe, the aortic component of S_2 diminishes and eventually disappears, resulting in a soft, single S_2. Often, with severe AS, S_2 is paradoxically split because of the prolonged ejection duration through the severely narrowed valve. S_3 is indicative of poor LV systolic function. An S_4 is common because of reduced LV compliance.

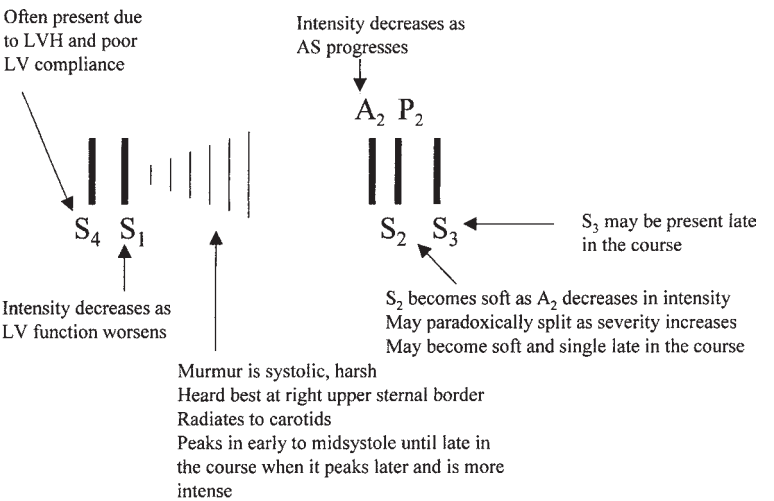

FIGURE 15.2 Auscultatory findings in aortic stenosis. LVH, left ventricular hypertrophy; LV, left ventricular.

TABLE 15.1 Physical Findings and Maneuvers Useful in Distinguishing Various Forms of Left Ventricle Outflow Tract Obstruction

Maneuver finding	Valvular	Supravalvular	Subvalvular	Hypertrophic cardiomyopathy
Pulse volume after PVC	Increases	Increases	Increases	Decreases
Valsalva effect on systolic murmur	Decreases	Decreases	Decreases	Increases
AR	Common	Rare	Common	Rare
S_4	Common	Uncommon	Uncommon	Common
Carotid pulse	Normal to anacrotic (parvus et tardus)	Unequal	Normal to anacrotic	Rapid jerky upstroke

AR, aortic regurgitation; PVC, premature ventricular contraction

(2) Careful examination for other murmurs should be performed. AS is often accompanied by AR. Maneuvers performed during the physical examination can help differentiate different types of LV outflow obstruction, whether this is at, below, or above the valve. These are summarized in Table 15.1.

3. **Diagnostic testing**
   a. The typical **electrocardiogram (ECG)** of a patient with isolated severe AS usually demonstrates left atrial abnormality (80% of cases) and LVH (85% of cases).
   b. **Chest radiography** can be entirely normal, even in patients with critical AS. The cardiac silhouette may become boot-shaped because of concentric LVH. Cardiomegaly may be identified if there is LV dysfunction or coexisting AR. Aortic valve and root calcification can be seen in adults with severe calcific, degenerative AS. Poststenotic dilation of the ascending aorta may be evident.
4. **Severity of AS**. The severity of AS is currently graded by ACC/AHA valve guidelines as follows:

Mild: valve area > **1.5 cm**^{2}, mean gradient < 25 mm Hg, or jet velocity < 3.0 m/s
Moderate: valve area **1.0 to 1.5 cm**^{2}, mean gradient 25 to 40 mm Hg, or jet velocity 3.0 to 4.0 m/s
Severe: valve area < **1.0 cm**^{2}, mean gradient > 40 mm Hg, or jet velocity > 4.0 m/s

The normal aortic valve opens to 3 to 4 cm^2.

5. **Echocardiography**
   a. **Transthoracic Doppler echocardiography** is the test of choice per ACC/AHA guidelines to establish the diagnosis of AS, to determine the cause and location, and to assess its severity. It should be performed when the diagnosis of AS is first suspected and information such as LV wall thickness, size, and function should also be obtained. After the diagnosis is established, patients should have frequent, regular clinical follow-up examinations to look for the development of symptoms. Echocardiographic follow-up can be tailored to the severity of disease: at least annually for severe AS and more frequently

as the severity increases. Development of new symptoms and signs should quickly prompt a repeat evaluation.

(1) The parasternal long-axis views, two dimensional and M-mode, provide valuable information for determining the mechanism and severity of AS. In this view, the coaptation line of the aortic valve is normally centered within the LVOT in a trileaflet valve. The leaflets of a bicuspid valve often have an eccentric closure line, typically posterior to the midline. Systolic leaflet doming can be seen in congenital AS and rheumatic AS. The degree of LVH, LV chamber enlargement, or left atrial enlargement can be quantitated using two-dimensional and M-mode imaging. The LVOT diameter used in the continuity equation is measured in the two-dimensional, parasternal long-axis view.

Subaortic stenosis and supravalvular AS may also be detected in this view. Subaortic stenosis may be evident as a membrane below the aortic valve with normal motion of the valve. Pulsed Doppler may indicate that the obstruction is occurring below the valve and 2 dimensional echocardiogram often shows AR due to the turbulent jet hitting aortic valve leaflets and causing leaflet scarring and impaired coaptation. In supravalvular AS, narrowing above the valve is evident on imaging and with Doppler.

(2) The parasternal short-axis view is the most useful view for establishing the cause of congenital AS. The number of commissures and the shape of the valve orifice should be assessed (Fig. 15.3). Trileaflet valves open

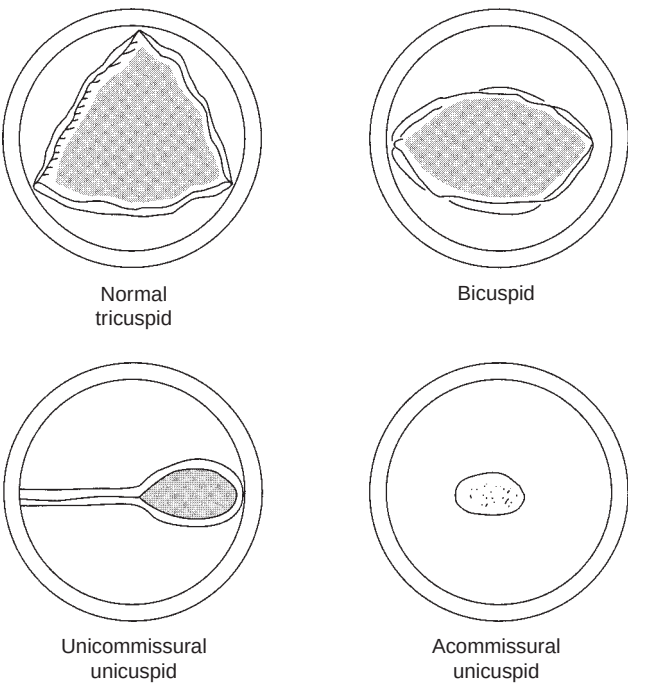

FIGURE 15.3 A schematic representation of parasternal short axis of a congenitally abnormal aortic valve.

as a triangle, whereas an elliptical opening suggests a bicuspid valve. In a unicuspid valve, the opening is elliptical but occurs across a radius rather than the diameter of the valve.

(3) The apical five-chamber and three-chamber views are well aligned with flow through the aortic valve. Continuous wave Doppler recordings across the aortic valve and pulsed wave Doppler flow in the LVOT proximal to the aortic valve are recorded in these views for the continuity equation.

(4) Continuous wave Doppler should be performed at multiple sites, including the suprasternal notch and the right sternal border, to ensure that the maximal velocity across the aortic valve is recorded. The dimensions of the ascending aorta should be measured, and coarctation in the descending aorta should be sought, especially in those with bicuspid aortic valves.

b. **Transesophageal echocardiography (TEE).** Planimetry of the aortic valve orifice is often possible with TEE and relates well to that measured by cardiac catheterization. Planimetry is difficult when the valve is extremely calcified. In bicuspid valve, the smallest area should be sought carefully, as the valve opening is not planar but rather forms a cone due to the doming of the valve as it opens. TEE is particularly useful for determining the morphologic features of the valve in congenital AS. TEE is often necessary to confirm the diagnosis of subaortic membrane and to differentiate it from hypertrophic cardiomyopathy or valvular AS.

c. **Dobutamine echocardiography and stress echocardiography.** Exercise testing in patients with asymptomatic AS may provide useful information such as exercise-induced symptoms or abnormal blood pressure response (ACC/AHA class IIb indication). Exercise testing is contraindicated (ACC/AHA class III indication) in symptomatic patients with AS. Dobutamine echocardiography may be useful in evaluating low-flow/low-gradient AS in patients with LV dysfunction (see Chapter 51 for further discussion).

6. **Hemodynamic calculations**

a. **Doppler echocardiography** is the standard modality used for the assessment of transvalvular pressure gradient and AVA.

(1) **Simplified Bernoulli equation ($\Delta P = 4v^2$)**, in which P is pressure and v is peak velocity of flow across the aortic valve, is used to estimate the peak instantaneous gradient. The mean gradient across the valve can be measured by calculating the area under the Doppler envelope. The peak velocity of flow across the aortic valve should be measured in three areas: the LV apex, the right sternal border, and the suprasternal notch. The highest measured velocity is used to calculate the peak transvalvular gradient. When stenosis is present at two levels (i.e., in LVOT and at the valve), the gradient across the LVOT reflects the integrated effects of the obstruction at both levels. It is usually impossible with Doppler to precisely differentiate the contribution of each level of obstruction to the total. This may be inferred by the analysis of the images, by TEE, or by direct measurement at cardiac catheterization.

(2) Calculation of AVA is based on the **continuity principle**, which states that the flow of an incompressible fluid in a closed system must remain constant. Flow in a vessel is the product of the cross-sectional area (A) of the vessel and the velocity (V). Area is calculated as πR^2 or $\pi \cdot D^2/4 = 0.785D^2$, where R is the radius of the vessel and D is the diameter. A schematic representation of the variables for calculating AVA is shown in Figure 15.4. The continuity equation for the aortic valve is as follows:

$$\text{Area}_{\text{aortic valve}} = \text{diameter}_{\text{LVOT}}{}^2 \times 0.785 \times \text{VTI}_{\text{LVOT}}/\text{VTI}_{\text{aortic valve}}.$$

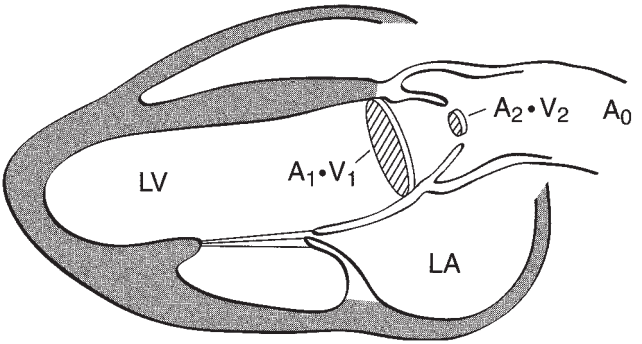

FIGURE 15.4 A schematic representation of parasternal long-axis view and the continuity principle. LV, left ventricle; LA, left atrium.

In the above equation, VTI is the time–velocity integral. The continuity equation is valid only for valvular AS. It cannot be used to assess valve area when there are stenoses in series such as valvular and subvalvular narrowing occurring simultaneously.

(3) Care should be taken to avoid measuring postextrasystolic beats. If the patient is in atrial fibrillation, 10 consecutive beats should be measured and averaged for both velocity measurements.

(4) During evaluation of an aortic valve prosthesis, the standard continuity equation cannot be used. Instead, the velocity ratio or **dimensionless index** is used to estimate the severity of prosthetic stenosis. It is calculated by dividing the peak velocity in the LVOT by the peak velocity through the aortic valve. **A dimensionless index of < 0.25 is generally accepted to represent severe stenosis**. This is also useful if the LVOT diameter is difficult to ascertain.

b. Cardiac catheterization was once considered the gold standard for the quantification of AS but is now contraindicated (ACC/AHA class III indication) in the routine evaluation of a patient when echo-Doppler studies are adequate and congruent with clinical findings.

(1) Preoperative catheterization. Patients > 50 years of age, patients with angina, and patients with significant risk factors for CAD should undergo coronary cineangiography before aortic valve operations (ACC/AHA class I indication).

(2) Catheter-derived hemodynamic data are indicated (ACC/AHA class I indication) to further evaluate the severity of AS when the clinical and echocardiographic findings diverge. Because cardiac catheterization findings often differ from those of echocardiography, it is important to understand the differences in what is being measured. The mean gradients obtained during catheterization should be equivalent to the mean gradients obtained by echocardiography. These correlate well when performed expertly and simultaneously. The peak gradient measured during catheterization is the peak-to-peak gradient, which is lower than the peak instantaneous gradient obtained with echocardiography (Fig. 15.5). In the setting of reduced cardiac output of any cause, the aortic gradient may be much lower and may be < 20 mm Hg in severe LV dysfunction despite critical AS.

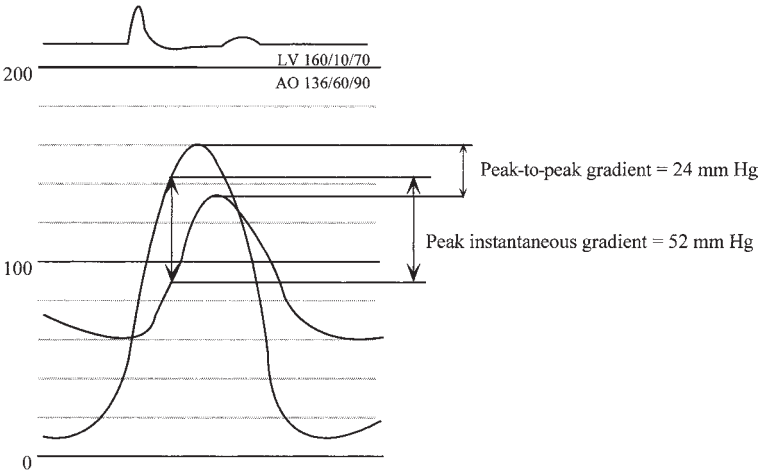

FIGURE 15.5 Simultaneous recording of LV and aortic pressures. LV, left ventricle; AO, aorta.

(3) The most precise measurement of transaortic valvular gradient is made with two different catheters (one in the LV cavity and the other in the ascending aorta) or with a double-lumen pigtail catheter. Because the two-catheter technique requires cannulation of both femoral arteries, another acceptable method of measuring the peak-to-peak gradient is catheter pullback from the left ventricle to the ascending aorta. A typical pressure tracing of simultaneous LV and aortic pressures is shown in Figure 15.5.

(4) Catheterization of the patient with severe AS should be performed with low-osmolar, nonionic contrast agents. These cause less hypotension due to peripheral arterial vasodilation, less bradycardia, less transient myocardial dysfunction, and less osmotic diuresis after the procedure. Left ventriculography should be avoided.

(5) The Gorlin formula is used to estimate AVA:

$$\text{AVA (cm}^2\text{)} = \text{cardiac output}/(44.3 \times \text{heart rate} \times \text{SEP} \times \sqrt{\text{MVG}}).$$

In the above equation, SEP is the systolic ejection period, defined as the time from aortic valve opening to closing (in seconds), and MVG is the mean valvular gradient (mm Hg). The **Gorlin** formula measures the **true anatomic area** of the aortic valve, as it has a correction factor (the discharge coefficient) to account for the difference of flow across the true anatomic valve versus the flow at the level of the vena contracta. **Continuity equation** measures the **physiologic area** (vena contracta) and as such is smaller than that measured by Gorlin.

An alternative measurement can be made by Hakki equation, which is a simplification of Gorlin formula, where the observation of heart rate × SEP approximates 1,000. This then simplifies the estimation of AVA:

$$\text{AVA (cm}^2\text{)} = \text{cardiac output}/\sqrt{\text{MVG}}.$$

F. Therapy

1. **Medical therapy.** The mainstay of therapy for severe AS is surgical replacement of the aortic valve. Onset of symptoms in patients with severe AS is associated with a marked reduction in lifespan when treated medically, rather than surgically. Medical therapy alone is ineffective for severe symptomatic valvular AS.
   a. **Antibiotic prophylaxis.** The updated 2007 AHA guideline on prevention of infective endocarditis has been extensively modified. Unless the patient has a valve prosthesis or prior history of infective endocarditis, antibiotic prophylaxis prior to dental procedures is no longer recommended in patients with valvular pathology.
   b. **Medical therapy in asymptomatic patients.** During the asymptomatic phase, therapy is directed at primary prevention of CAD, maintenance of sinus rhythm, and blood pressure control.
   c. **Medical therapy in symptomatic patients.** Medical therapies may be necessary in symptomatic patients with severe AS who are awaiting surgery or who are considered inoperable and require palliation. Therapy for heart failure is directed at relief of pulmonary congestion. This is usually achieved with cautious use of diuretics. Overly aggressive diuresis can cause hypotension if hypovolemia significantly impairs cardiac output by diminishing preload. Nitrates can also cause hypotension and syncope by reducing preload and should be avoided or used with extreme caution. Thus, the management of symptomatic patients with AS and CAD is difficult, and urgent surgery is the optimal treatment where feasible. Digoxin is used for symptom relief in the setting of impaired LV systolic function and volume overload, particularly if atrial fibrillation develops.
   d. **Vasodilator therapy** has been relatively contraindicated in patients with AS, because lowering SVR in the setting of a fixed cardiac output may cause syncope, especially in the ambulatory setting. However, patients with severe heart failure and LV dysfunction with severe AS may benefit from the careful titration of intravenous nitroprusside in the intensive care unit with concomitant invasive arterial and pulmonary artery monitoring. One study suggests an improvement in hemodynamic indices with this approach. This therapy is used only as a bridge to definitive surgical therapy. Intraaortic balloon counterpulsation is another strategy that can be used while patients with LV dysfunction and severe AS in cardiogenic shock are worked up toward urgent surgery.
   e. **Treatment of hyperlipidemia.** The association between AS and risk factors for atherosclerosis has prompted trials with statins to retard the progression of AS. Several studies suggested that when statin therapy is indicated based on current guidelines for hyperlipidemia it is associated with a modest effect in slowing the rate of progression of AS. However, in more recent randomized controlled trials of patients with calcific AS, where statin therapy was not otherwise mandated, statins had no effect on AS progression. As such, there is currently no indication for statin use specific to AS, although in hyperlipidemic patients with AS, aggressive lowering of LDL level with statins appears warranted. In patients with supravalvular AS due to severe familial hyperlipidemia, improvement in the obstruction may occur after low-density lipoprotein apheresis.
2. **Percutaneous aortic balloon valvuloplasty (PABV) and percutaneous valve replacement**
   a. In pediatric congenital, noncalcific AS, PABV is a safe and effective therapy, comparable to surgical repair or replacement. The goal of PABV in congenital AS is to achieve a 60% to 70% reduction in the measured peak-to-peak transvalvular gradient. Redilatation or AVR becomes necessary within 10 years of

the initial PABV in > 50% of children. AR is well recognized as a potential early or late complication of PABV, although moderate-to-severe AR occurs in a minority of cases.

b. In adults, PABV is not an effective long-term therapy for AS compared with surgical AVR. Although PABV initially achieves effective relief of LVOT obstruction (up to 50% improvement in AVA), nearly 50% of patients have restenosis within 6 months. Moreover, PABV does not prolong survival in adults with AS. For these reasons, PABV is mainly used for palliation of symptoms or as a bridge to AVR (ACC/AHA class IIb indication). PABV is generally not recommended in asymptomatic patients with severe AS who are undergoing urgent noncardiac surgery. It is recommended that these patients undergo vigilant monitoring with careful hemodynamic monitoring.

c. Percutaneous replacement of the aortic valve. An exciting strategy currently in development is the placement of a stented bioprosthetic valve over the native aortic valve, either percutaneously from an arterial site (usually in the femoral or iliac artery) or transapically from an incision made at the LV apex on the chest wall (transcatheter aortic valve replacement [TAVR]). The native valve is initially dilated with a balloon. The stented valve is deployed during rapid pacing to allow adequate time for successful placement. Currently, two percutaneous valves are available in the U.S. (Edwards Sapien and CoreValve). Of these, Edwards Sapien valve has gained approval from FDA in 2011 as it has been shown to improve survival in inoperable patients compared to medical therapy. Trials for both valves are currently ongoing. As an option to treat patients who are otherwise not candidates for open surgical replacement, TAVR provides a viable alternative over medical or surgical management. However, the technology is still developing. Paravalvular leak is still common following valve deployment, and the technique has considerable morbidity, not least as it has been used up to now in very ill patients (see Chapter 66).

3. Surgical therapy. AVR is the surgical treatment of choice. It is preferred over repair because debridement of aortic valve calcification often results in early postoperative AR from leaflet fibrosis and retraction, a process that progresses over time.

a. Recommendations for the use of AVR in patients with AS according to the modified 2006 ACC/AHA guidelines are given in Table 15.2. The major indications are for severe AS with symptoms or where other cardiac surgery is needed or when LV dysfunction develops as a result of severe AS.

b. Surgical mortality rate varies among patients with AS depending on age and other comorbidities including concomitant CAD. In an otherwise healthy individual, mortality rate for isolated AVR in experienced centers should be < 1%. When this is the case, the 2006 ACC/AHA guidelines suggest that prophylactic surgical intervention may be considered in severe AS, even in the absence of symptoms, especially if the valve is calcified and therefore the disease is likely to progress rapidly (ACC/AHA class IIb indication).

Successful AVR is feasible and normalizes life expectancy, even in very elderly patients without multiple comorbidities. Surgical options include pulmonary valve autograft (i.e., Ross procedure), aortic valve homograft conduit, a pericardial or porcine bioprosthesis, or a mechanical valve. The relative advantages, disadvantages, and indications for use of the different prostheses are outlined in Chapter 18.

(1) In the Ross procedure, the pulmonary valve and main pulmonary artery are removed as a unit and placed in the aortic position with reimplantation of the coronary arteries. A pulmonary homograft is placed in the pulmonic position. This procedure is best suited for pediatric and adolescent patients

TABLE 15.2 Recommendations for Aortic Valve Replacement in Patients with Aortic Stenosis

Class I

1. AVR is indicated for symptomatic patients with severe AS
2. AVR is indicated for patients with severe AS undergoing CABG or surgery on the aorta or other heart valves
3. AVR is recommended for patients with severe AS and LV systolic dysfunction (ejection fraction < 0.50)

Class IIa

AVR is reasonable for patients with moderate AS undergoing CABG or surgery on the aorta or other heart valves

Class IIb

1. AVR may be considered for asymptomatic patients with severe AS and abnormal response to exercise (e.g., development of symptoms or asymptomatic hypotension)
2. AVR may be considered for adults with severe asymptomatic AS if there is a high likelihood of rapid progression (age, calcification, and CAD) or if surgery might be delayed at the time of symptom onset
3. AVR may be considered in patients undergoing CABG who have mild AS when there is evidence, such as moderate-to-severe valve calcification, that progression may be rapid
4. AVR may be considered for asymptomatic patients with extremely severe AS (aortic valve area < 0.6 cm^2, mean gradient > 60 mm Hg, and jet velocity > 5.0 m/s) when the patient's expected operative mortality is 1.0% or less

Class III

AVR is not useful for the prevention of sudden death in asymptomatic patients with AS who have none of the findings listed under the class IIa/IIb recommendations

AVR, aortic valve replacement; AS, aortic stenosis; CABG, coronary artery bypass grafting; LV, left ventricular; CAD, coronary artery disease.

From Bonow RO, Carabello B, Chatterjee K, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: an executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease). *J Am Coll Cardiol*. 2006;48: 598–675, with permission from Elsevier.

with growth potential, because the autograft is capable of growth, does not require anticoagulants, and has an excellent hemodynamic profile. The procedure, however, is long and technically difficult and subsequently turns a single-valve problem into a double-valve problem. Problems with pulmonary homograft are common in adults who underwent this operation.

Aortic valve homografts have been used to treat younger patients, especially those who wish to avoid anticoagulation, in the hope that greater durability of this valve might result than with a bioprosthesis. Unfortunately, more recent data suggest that any durability advantage of a homograft over a bioprosthesis in middle-aged patients is slight. Moreover, the homograft tends to calcify and is often difficult to remove at subsequent reoperations. Therefore, enthusiasm for homografts has waned, except in the setting of endocarditis of native or prosthetic valves with pyogenic complications such as abscess or fistula or when the LVOT is small, in which case homografts maximize the flow area and minimize the pressure gradient.

(2) **Bioprostheses** include porcine heterografts and bovine pericardial prostheses. These valves are most often used to treat patients older than 60 years because structural deterioration is much slower in this age group compared with younger patients. These valves have a low risk for thromboembolism and do not necessitate long-term anticoagulation. Because of the sewing ring and struts, all prostheses, both mechanical and biologic, have a pressure gradient across them, even with normal function. The largest possible valve should be inserted to minimize this pressure gradient. The threshold to insert bioprostheses at a younger age continues to decline given the excellent quality of life these afford.

(3) **Mechanical valves.** The most commonly used mechanical prostheses include the St. Jude, Medtronic-Hall, and CarboMedics prostheses. These all require anticoagulants to minimize the risk of valve thrombosis and thromboembolism. These valves are durable if anticoagulation is maintained and careful antibiotic prophylaxis is used over the years. Mechanical valves are used with caution in older patients (> 65 years) given the substantial increase in anticoagulation-related hemorrhage and resultant mortality in this population.

G. Special considerations

1. Management of asymptomatic patients with severe AS

a. High-risk patients. Most asymptomatic AS patients have low mortality and morbidity rates. A minority of asymptomatic patients, however, may die suddenly or have rapid progression of disease. These patients may benefit from AVR in the absence of symptoms. Accurate identification of such patients has been difficult. A transaortic flow velocity of > 4 m/s predicts a 70% likelihood of needing an AVR within the subsequent 2 years, whereas a velocity of < 3 m/s corresponds to a low likelihood (< 15%) of needing an AVR in the subsequent 5 years. Patients with highly calcified valves and a rapid increase in the pressure gradient may be considered for elective AVR if the transaortic flow velocity is > 4 m/s. Other reasonable indications for AVR in patients with severe asymptomatic AS include LV dysfunction attributable to AS, exercise-induced hypotension, pulmonary hypertension (> 60 mm Hg), a high likelihood of rapid progression, and before pregnancy.

b. Coronary artery bypass grafting (CABG) in moderate AS. Is there a need for AVR? Studies suggest a benefit of concomitant AVR in patients undergoing CABG who have an AVA of < 1.5 cm^2. Although concomitant AVR increases the risk of the initial surgery, the need for reoperation is significantly lower in these patients, and this may provide a survival benefit. Patients with mild AS who have evidence of moderate/severe calcification with a high likelihood of rapid progression may also undergo AVR during CABG.

2. Patients with AS and severely reduced ejection fraction.

LV dysfunction in patients with AS can result from the afterload stress imposed on the left ventricle by the stenotic valve or from primary contractile dysfunction (e.g., result of other causes of cardiomyopathy). When LV dysfunction results primarily from afterload mismatch, surgical correction of AS often results in improvement or normalization of LV function. In contrast, patients with primary contractile dysfunction have an overall poor prognosis and are unlikely to benefit from AVR. It is important to determine the cause of LV dysfunction in patients with severe AS for prognostic and therapeutic purposes. These patients should be considered in three major groups: those with high transvalvular gradients (mean gradient > 40 mm Hg), those with low transvalvular gradients (mean gradient < 30 mm Hg), and those with aortic pseudostenosis.

a. High transvalvular gradient. A high transvalvular gradient is a surrogate measure of high afterload mismatch. When the transvalvular gradient is

substantial (e.g., mean gradient > 40 mm Hg), surgical correction of AS can result in normalization of LV function.

b. **Low transvalvular gradient.** Patients with true anatomically severe AS (AVA < 1.0 cm^2) and low transvalvular gradients (mean gradient < 30 mm Hg) have a very poor prognosis without surgery. Despite a substantial operative mortality, survival appears improved in those treated surgically, especially if they demonstrate **contractile reserve** when challenged with dobutamine. Contractile reserve is defined as the ability to increase transvalvular flow by > 20% from baseline. Dobutamine infusion may help identify the subset of patients with low-gradient AS who benefit from AVR.

c. **Aortic pseudostenosis.** Patients with primary contractile dysfunction and mild AS can have a falsely small calculated valve area, mimicking severe AS. This phenomenon, called aortic pseudostenosis, occurs principally because the force generated by the weakened left ventricle is not sufficient to open a mildly stenotic valve. Differentiating low-gradient, anatomically severe AS from aortic pseudostenosis is usually accomplished by one of two methods: increasing the cardiac output with dobutamine or decreasing the total peripheral resistance with vasodilators such as nitroprusside. Patients with truly severe AS experience a parallel increase in cardiac output and in the transvalvular pressure gradient after dobutamine infusion (in the echocardiography or catheterization laboratory). The calculated valve area, therefore, does not increase. In contrast, dobutamine infusion in patients with aortic pseudostenosis results in an increase in cardiac output without a significant increase in the transvalvular pressure gradient (the mildly stenotic valve is able to accommodate the increase in blood flow). As a result, the calculated AVA increases significantly (≥0.3 cm^2). Nitroprusside infusion can also be used to differentiate true stenosis from pseudostenosis by lowering SVR. In true severe AS, the transvalvular gradient increases in response to vasodilators, but the fixed LV outflow obstruction does not allow cardiac output to increase concomitantly. In pseudostenosis, the valve resistance is small, and a decrease in SVR is accompanied by a significant increase in cardiac output and a decrease in the transvalvular gradient. The calculated valve area, therefore, remains the same or decreases in true stenosis and increases in pseudostenosis. The differentiation of true severe AS from aortic pseudostenosis is important because patients with aortic pseudostenosis have primary contractile dysfunction and are unlikely to benefit from AVR alone.

3. **Severe AS with low gradients and preserved left ventricular ejection fraction (LVEF).** Several patients present with severe AS with seemingly normal left ventricular function and paradoxically low gradients. This population appears to be composed of two groups: one with low flow and relatively high afterload and the other in whom the discrepancy between gradients and area may be due to errors in measurement. There is evidence that those with true low flow and severe AS are more likely to be women with small ventricles, significant LVH, and hypertension. In this group, outcome is worse than expected, as surgery may be delayed based on the discrepancy between AVA and gradients even in the presence of symptoms. It is important to be aware of this group and to ensure that those who have severe AS and low flow are considered for early surgery once symptoms occur.
4. **Subaortic stenosis.** Surgical removal of the membrane leading to subaortic obstruction is indicated for symptomatic patients, for asymptomatic patients with a pressure gradient greater than 50 mm Hg, and if there is evidence of concomitant moderate or greater AR as a result of damage to the aortic valve leaflets from the turbulent subvalvular jet.

TABLE 15.3 Major Causes of Chronic Aortic Regurgitation

Leaflet abnormalities	Aortic root or ascending aorta abnormalities
Rheumatic fever	Age-related aortic dilation
Infective endocarditis	Annuloaortic ectasia
Trauma Myxomatous degeneration	Cystic medial necrosis of the aorta (isolated biscuspid aortic valve or Marfan's syndrome)
Congenital aortic regurgitation	Systemic hypertension
Systemic lupus erythematosus	Aortitis (syphilis and giant cell arteritis)
Rheumatoid arthritis	Reiter's syndrome
Ankylosing spondylitis	Ankylosing spondylitis
Takayasu's arteritis	Behçet's syndrome
Whipple's disease	Psoriatic arthritis
Crohn's disease	Osteogenesis imperfecta
Drug-induced valvulopathy	Relapsing polychondritis
	Ehlers-Danlos syndrome

II. AORTIC REGURGITATION

A. Introduction. AR can develop from primary disease of the valve leaflets or from abnormalities of the aortic root or ascending aorta. The chronic and acute forms of AR are distinct disease entities, with different causes, clinical presentations, natural histories, and treatment strategies.

B. Etiology

1. **Chronic AR.** Disease of the valve leaflets can cause AR by inadequate leaflet coaptation, leaflet perforation, or leaflet prolapse. The most common causes of leaflet abnormalities and aortic root abnormalities that lead to the gradual development of AR are given in Table 15.3. Subaortic stenosis can also cause AR due to a high-velocity jet of blood that is a result of the outflow obstruction hitting the aortic valve, causing damage to the leaflets. Perimembranous ventricular septal defects are associated with AR as well. In addition to disease of native valve leaflets, structural deterioration of bioprosthetic valve leaflets is an important cause of chronic AR.
2. **Acute AR.** Acute AR can also result from abnormalities in the valve leaflets or in the aortic root. The causes of acute AR are limited (Table 15.4).

TABLE 15.4 Major Causes of Acute Aortic Regurgitation

Leaflet abnormalities	Aortic root or ascending aorta abnormalities
Traumatic rupture	Acute aortic dissection
Acute infective endocarditis	Perivalvular leak or dehiscence of prosthetic valves
Acute prosthetic valve dysfunction	
Post aortic balloon valvuloplasty	

C. Pathophysiology

1. **Chronic AR.** AR results in diastolic regurgitation of LV stroke volume. This produces an increase in LV end-diastolic volume, thereby raising wall tension (i.e., Laplace's law). The ventricle responds to added wall tension by compensatory eccentric hypertrophy of myocytes. As a result, during the chronic compensated phase of AR, the left ventricle is able to adapt to an increase in diastolic volume without a significant increase in end-diastolic pressure. The left ventricle produces a larger total stroke volume with each contraction, preserving normal effective forward stroke volume. Over time, however, progressive interstitial fibrosis reduces LV compliance, leading to the chronic decompensated phase. Chronic volume overload results in impaired LV emptying, an increase in LV end-systolic volume and end-diastolic pressure, further cardiac dilation, and a fall in the ejection fraction and forward cardiac output.
2. **Acute AR.** Acute AR is usually a hemodynamic emergency because the left ventricle does not have sufficient time to adapt to the rapid increase in LV volume. The effective forward stroke volume and cardiac output fall acutely, potentially resulting in hypotension and cardiogenic shock. The sudden increase in LV diastolic pressure initially causes preclosure of the mitral valve in early diastole, protecting the pulmonary vasculature from elevated diastolic pressure. However, further LV decompensation leads to diastolic mitral regurgitation (MR), which allows transmission of elevated diastolic pressure to the pulmonary vascular bed, resulting in pulmonary edema. The tachycardia that accompanies cardiac deterioration helps shorten the diastolic-filling period during which the mitral valve is open.

D. History and clinical presentation

1. **Chronic AR** is usually asymptomatic for a long time. After the development of LV dysfunction, patients gradually experience symptoms related to pulmonary congestion, including increased dyspnea with exertion, orthopnea, and paroxysmal nocturnal dyspnea. LV enlargement frequently produces an uncomfortable sensation in the chest that is exaggerated after premature ventricular contractions and in the supine position. Although angina is uncommon, it can be produced by latent CAD, decreased diastolic coronary perfusion pressure, nocturnal bradycardia and fall in arterial diastolic pressure, marked LVH, and subendocardial ischemia.
2. **Acute AR.** Patients with acute, severe AR usually present with signs of sudden hemodynamic deterioration such as weakness, altered mental status, severe shortness of breath, or syncope. If left untreated, these patients quickly progress to total cardiovascular collapse. When severe chest pain is part of the initial clinical presentation, aortic dissection must be strongly suspected.

E. Physical findings

1. **Chronic AR.** Patients with chronic AR can have a wide array of physical findings, especially during examination of the peripheral pulses and cardiac auscultation. The physical examination may yield clues about the cause of AR. Patients with AR should be examined for the peripheral manifestations of infective endocarditis, signs of Marfan's syndrome, evidence of chronic aortic dissection, and signs of collagen vascular disorders.
   a. **Peripheral pulse examination.** The increased total stroke volume in chronic AR leads to an abrupt increase in arterial pressure during systole, followed by a rapid fall in arterial pressure during diastole. The widened pulse pressure accounts for a number of physical findings associated with chronic AR (Table 15.5). Patients with chronic AR may exhibit a bisferiens pulse, characterized by double systolic peaks with increased amplitude. The signs of hyperdynamic circulation are not specific to AR and can be seen in conditions that cause high-output heart failure, including sepsis, anemia, thyrotoxicosis, beriberi, and arteriovenous fistula.

TABLE 15.5 Physical Signs Associated with Hyperdynamic Pulse in Chronic Aortic Regurgitation

Physical sign	Description
Water hammer or Corrigan's pulse	Rapid upstroke followed by quick collapse
de Musset's sign	Head bob with each heartbeat
Traube's sign	Pistol shot sounds heard over the femoral arteries in both systole and diastole
Müller's sign	Systolic pulsation of the uvula
Duroziez's sign	Systolic murmur over the femoral artery when compressed proximally and diastolic murmur when compressed distally or systolic–diastolic murmur with increasing compression over femoral artery
Quincke's sign	Capillary pulsations visible in the lunula of the nail bed
Hill's sign	Popliteal cuff systolic pressure exceeding brachial cuff systolic pressure by > 60 mm Hg
Becker's sign	Arterial pulsations visible in the retinal arteries and pupils

b. Palpation. With severe AR, the apical impulse is typically enlarged and displaced lateral to the midclavicular line in the fifth intercostal space because of LV enlargement. The impulse may be sustained and hyperdynamic. A diastolic thrill may be palpable in the second left intercostal space, as may a systolic thrill caused by increased aortic flow.

c. Auscultation. The main auscultatory findings are outlined in Figure 15.6.

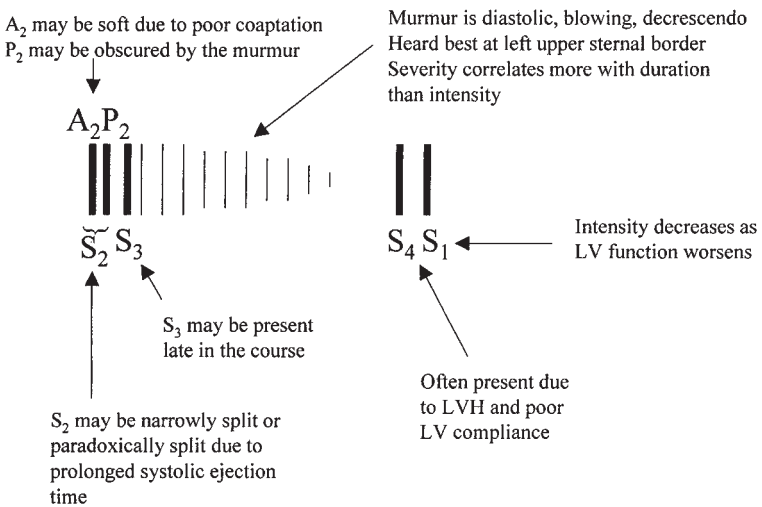

FIGURE 15.6 Physical findings in aortic regurgitation. LV, left ventricular; LVH, left ventricular hypertrophy.

(1) **Heart sounds.** S_1 may be diminished in the presence of PR-interval prolongation, LV dysfunction, or preclosure of the mitral valve. S_2 may be soft, singly split (P_2 obscured by the diastolic murmur) or paradoxically split. An S_3 may be heard with severe LV dysfunction. An S_4 is often present and represents left atrial contraction into a poorly compliant left ventricle.

(2) **Diastolic murmur.** The hallmark murmur of AR is a blowing, diastolic, decrescendo murmur that starts immediately after A_2 and is best heard in the left upper sternal border with the patient sitting up and leaning forward slightly in full expiration. In general, the severity of AR correlates with the duration of the murmur more than with its intensity. Early in the course of disease, the murmur is typically short. As the disease progresses, the murmur may become pandiastolic. In the end stages of AR, the murmur may shorten again because of rapid equilibration of pressures in the aorta and left ventricle from an elevated LVEDP. In this situation, other signs of severe AR are usually present.

(3) A **second diastolic murmur** may be audible at the apex in severe AR. The Austin Flint murmur is a middle-to-late diastolic rumble that is believed to be caused by vibration of the anterior mitral leaflet as it is struck by the regurgitant jet or by turbulence in the mitral inflow from partial closure of the mitral valve by the regurgitant jet. Unlike the murmur of true valvular mitral stenosis, the Austin Flint murmur is not associated with a loud S_1 or with an opening snap.

(4) A short **midsystolic ejection murmur** may be audible at the base of the heart, radiating to the neck. It reflects the increased ejection rate and large stroke volume traversing the aortic valve.

2. **Acute AR.** The physical examination of patients with acute AR differs considerably from that of patients with chronic AR. The physical examination may be most notable for signs of hemodynamic compromise, such as hypotension, tachycardia, pallor, cyanosis, diaphoresis, cool extremities, and pulmonary congestion.

   a. **Peripheral examination.** The signs of hyperdynamic circulation that characterize chronic AR are often absent in acute AR. The pulse pressure may be normal or only slightly widened. The heart size is often normal, and the point of maximal intensity is not displaced laterally. When aortic dissection is suspected, blood pressures should be taken in all extremities to detect the differences.

   b. **Heart sounds.** S_1 may be diminished due to preclosure of the mitral valve. Pulmonary hypertension may manifest as an increased P_2 component of the second heart sound. An S_3 often accompanies cardiac decompensation.

   c. **Murmurs.** The early diastolic murmur of acute AR is shorter and lower in pitch than the murmur of chronic AR. In severe, acute AR, the murmur may not be audible when the diastolic pressure in the left ventricle and aorta equilibrates. The systolic murmur reflecting increased flow across the aortic valve may be heard but is usually not loud. The Austin Flint murmur, if present, is short.

F. Laboratory evaluation

1. **ECG.** The typical ECG in chronic AR shows LVH, left-axis deviation, and left atrial abnormality. Conduction abnormalities are unusual but can occur after the development of LV dysfunction. Premature atrial and ventricular beats are common. Sustained supraventricular or ventricular tachyarrhythmias are uncommon in the absence of LV dysfunction or concomitant mitral valve disease. In acute AR, the ECG is usually notable only for nonspecific ST-T–wave abnormalities.

2. **Chest radiograph.** In chronic AR, the chest radiograph may reveal marked cardiomegaly, with the heart being displaced inferiorly and leftward. Dilation of the aortic knob and root may be seen. In acute AR, the LV and left atrial dimensions are usually normal. Aortic dissection can lead to a widened mediastinum and/or a widened cardiac silhouette due to pericardial effusion. The chest radiograph is notable for signs of pulmonary congestion.
3. **Echocardiography.** Two-dimensional and M-mode echocardiography are useful in determining the cause of AR, evaluating the aortic root, and assessing the overall LV size and function. Doppler echocardiography is useful for detecting AR and estimating severity. There are several different methods of estimating the severity of AR with color Doppler, pulsed wave Doppler, and continuous wave Doppler ultrasonography.
   a. **Two-dimensional and M-mode echocardiography.** The cause of AR can be assessed using two-dimensional echocardiography. Rheumatic AR typically causes thickening and retraction of the leaflet tips, leading to failure of cusp apposition. Bacterial endocarditis, which can cause leaflet fibrosis and retraction, leaflet perforation, or flail of the valve cusp, should be suspected if a vegetation is detected. Prolapse of the aortic valve cusps can occur in many conditions, including infective endocarditis, bicuspid aortic valve, myxomatous degeneration, and Marfan's syndrome. Aortic root abnormalities are also well visualized in the parasternal long-axis view. Aortic root dilation is most often idiopathic, although Marfan's syndrome, Ehlers-Danlos syndrome, ankylosing spondylitis, Reiter's syndrome, rheumatoid arthritis, syphilis, and giant cell arteritis are other potential causes. Symmetric dilation of the aortic root produces a central jet of AR, and focal dilation causes an eccentric jet. In the parasternal long axis, the transducer should be moved up one interspace to assess the ascending aorta. Infective destruction of the aortic wall and proximal aortic dissection flaps may occasionally be visualized on transthoracic images. M-mode echocardiography may reveal **premature closure of the mitral valve in severe, acute AR**. In acute AR and chronic AR, the regurgitant jet can strike the anterior mitral valve leaflet, causing it to reverberate or "flutter" in diastole. Reversed doming of the anterior mitral leaflet may be seen on two-dimensional imaging and generally indicates grade 3 to 4+ AR.
   b. **Doppler and color flow imaging.** Doppler and color flow echocardiography is used to detect AR and to assess its severity. AR is identified by Doppler imaging as high-velocity pandiastolic flow originating immediately under the aortic valve. Color flow imaging allows the assessment of jet origin, size, and direction. Continuous wave Doppler provides measurement of jet velocity and timing of flow. The maximum length of the AR jet correlates poorly with severity of regurgitation when assessed angiographically. Several other Doppler measures are used to estimate the severity of AR (Table 15.6). The ratio of the jet width to LVOT diameter is measured in the parasternal long-axis view and correlates well with the angiographic severity of AR. The pressure half-time of the aortic regurgitant velocity is defined as the time required for the pressure gradient across the aortic valve to fall to half of its initial value. The pressure half-times of patients with mild, moderate, and severe AR have demonstrated considerable overlap. In general, shorter pressure half-times are associated with increased severity of AR, and a pressure half-time of < 200 milliseconds is nearly always associated with severe AR. Quantitation of regurgitant volume and regurgitant fraction provides the most direct correlation with quantitative angiographic estimates of AR severity. Regurgitant volume is the difference between the stroke volume across the LVOT (representing the sum of forward flow and regurgitant flow) and

TABLE 15.6 Echo-Doppler Assessment of Aortic Regurgitation Severity

	Aortic regurgitation		
	Mild	**Moderate**	**Severe**
Qualitative			
Angiographic grade	1+	2+	3–4+
Color Doppler jet width	Central jet, width < 25% of LVOT	➢ Mild but no signs of severe AR	Central jet, width > 65% LVOT
Doppler vena contracta width (cm)	< 0.3	0.3–0.6	> 0.6
Quantitative (cath or echo)			
Regurgitant volume (mL/beat)	< 30	30–59	≥60
Regurgitant fraction (%)	< 30	30–49	≥50
Regurgitant orifice area (cm^2)	< 0.10	0.10–0.29	≥0.30

Left ventricular size			Increased

AR, aortic regurgitation; LVOT, left ventricular outflow tract.

From Bonow RO, Carabello B, Chatterjee K, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: an executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease). *J Am Coll Cardiol.* 2006;48:598–675, with permission from Elsevier.

that across the mitral valve inflow (representing forward flow), provided there is no significant MR. The regurgitant fraction is the ratio of the regurgitant volume divided by the LVOT stroke volume. The proximal isovelocity surface area (PISA) method is also used for estimating AR severity. The PISA method is used to calculate the effective regurgitant orifice (ERO) area. An ERO area ≥ 0.30 cm^2 is indicative of severe AR. The presence of a proximal convergence area on transthoracic echocardiogram at the aortic valve is indicative of at least moderate AR. Pulsed wave Doppler echocardiography should be performed in the proximal descending aorta to establish the presence of diastolic flow reversal. Some degree of flow reversal is normally seen early in diastole due to reflux of blood into the coronary vasculature, but if this is > 40 cm/s and continues throughout diastole, then severe AR is likely, especially if this persists in the abdominal aorta. Flow reversal may also be seen with other conditions that cause blood to leak out of the arterial system such as patent ductus arteriosus or sizeable arteriovenous fistula.

c. TEE is used to rule out vegetation or aortic valve ring abscess in patients who may have bacterial endocarditis. In pure AR, vegetation typically occurs on the LV side of the aortic valve. TEE is also used to visualize congenital valvular abnormalities (e.g., bicuspid valve) and to exclude aortic dissection.

d. Stress echocardiography is useful for assessing the ability to exercise. However, a fall in LVEF on exercise is less predictive of occult contractile dysfunction in severe AR than it is in MR. In AR, afterload often increases substantially on exercise, precipitating a fall in ejection fraction. A fall in LVEF on stress echocardiography alone is not a primary indication for valve surgery.

4. **Cardiac catheterization.** Cardiac catheterization is not necessary for all patients with chronic AR unless there are concerns about AR severity, hemodynamic abnormalities, or LV function, despite noninvasive testing and the physical examination. All patients older than 50 years with severe AR should undergo coronary cineangiography before any definitive surgical procedure on the valve to detect CAD. The decision to perform cardiac catheterization in younger patients should be made on an individual basis after assessment of the patient's cardiac risk profile. Catheter manipulation in patients with AR may be difficult because of dilation of the ascending aorta. Caution should be exercised when manipulating catheters in patients with Marfan's syndrome or cystic medial necrosis of the aortic wall to minimize the risk of vascular trauma. In addition to conventional coronary cineangiography, aortography should be performed to evaluate the degree of AR. The grading of AR by angiography is given in Table 15.7. Right heart catheterization may be helpful in certain circumstances, such as new-onset heart failure or combined AR and AS.

G. Natural history. Moderate-to-severe AR may have a good prognosis for many years, provided the patient is asymptomatic and does not exhibit signs of LV dysfunction or severe dilation. Asymptomatic patients with normal LV function require AVR at a rate of only 4% per year. Ninety percent of such patients remain asymptomatic at 3 years, 81% at 5 years, and 75% at 7 years after the diagnosis is made. Patients with mild-to-moderate AR have had a 10-year survival rate of 85% to 95%. Patients with moderate-to-severe AR treated with medical therapy have a 5-year survival rate of 75% and a 10-year survival rate of 50%. After the development of LV dysfunction, progression to symptoms is greatly accelerated, with rates approaching 25% per year. When symptoms develop, there is a rapid decline in functional status. Without surgical intervention, symptomatic patients usually die within 4 years of the onset of angina and within 2 years of the onset of heart failure. Sudden death may occur among patients with severe, symptomatic AR. Sudden cardiac death is frequently the result of ventricular arrhythmias that are primary (in the context of LVH or dysfunction) or secondary, resulting from myocardial ischemia. It has become clear that the various dimensions used to guide surgery in AR are relative and should be interpreted in the context of patient size and gender.

H. Therapy

1. **Medical therapy**
   a. **Chronic AR**
      (1) **Medical therapy.** Vasodilators, such as hydralazine, angiotensin-converting enzyme (ACE) inhibitors, and calcium channel blockers, have been used in the treatment of chronic AR to reduce the severity of regurgitation and help delay surgical intervention. There is conflicting evidence of their value (Table 15.8). Current ACC/AHA guidelines contraindicate their use (ACC/AHA class III indication) as an alternative to surgery when surgical intervention is indicated in a patient with acceptable surgical risk.

TABLE 15.7 Angiographic Grading of Aortic Regurgitation

Degree of aortic regurgitation	Left ventricular opacification	Rate of clearing
Mild (1+)	Faint, incomplete	Rapid
Moderate (2+)	Faint, complete	Rapid
Moderate to severe (3+)	Equal to aortic opacification	Intermediate
Severe (4+)	Greater than aortic opacification	Slow

TABLE 15.8 Indications for Vasodilator Therapy in Chronic Severe Aortic Regurgitation

Indication	Class
Chronic therapy in patients with severe regurgitation who have symptoms and/or LV dysfunction when surgery is not recommended because of additional cardiac or noncardiac factors	I
Short-term therapy to improve the hemodynamic profile of patients with severe heart failure symptoms and severe LV dysfunction prior to proceeding with AVR	IIa
Long-term therapy in asymptomatic patients with severe regurgitation who have LV dilation but normal systolic function	IIb
Not indicated for long-term therapy in asymptomatic patients with mild-to-moderate AR and normal LV systolic function	III
Not indicated for long-term therapy in asymptomatic patients with LV systolic dysfunction who are otherwise candidates for valve replacement	III
Not indicated for long-term therapy in symptomatic patients with either normal LV function or mild-to-moderate LV systolic dysfunction who are otherwise candidates for valve replacement	III

AR, aortic regurgitation; AVR, aortic valve replacement; LV, left ventricular.

From Bonow RO, Carabello B, Chatterjee K, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: an executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease). *J Am Coll Cardiol*. 2006;48:598–675, with permission from Elsevier.

Vasodilators are recommended in nonsurgical candidates with severe, chronic AR who develop symptoms or LV dysfunction (ACC/AHA class I indication). Vasodilators may also be reasonable for short-term therapy, improving the hemodynamics in patients with severe heart failure and LV systolic dysfunction prior to AVR. In asymptomatic patients, long-term vasodilator therapy may be considered for those with severe AR and normal LV systolic function who begin to demonstrate LV dilation. Long-term vasodilator therapy is not recommended for asymptomatic patients with mild-to-moderate AR and normal systolic function. These patients have a good prognosis and do not appear to benefit from vasodilator therapy. Although asymptomatic patients with LV systolic dysfunction or symptomatic patients may be treated with vasodilators in the short term, appropriate surgical candidates should be referred for AVR, and vasodilators should be continued on a long-term basis only if LV systolic dysfunction persists after AVR. The evidence for the use of specific vasodilator agents has been variable. Hydralazine was found to improve LV systolic function and to reduce LV chamber dimensions in some studies. Nifedipine was found to reduce LV volume and increase LVEF in a group of asymptomatic patients who were followed for 1 year. When compared with digoxin, nifedipine slowed the progression of LV dysfunction and delayed the time to surgical treatment in an unblinded, randomized study over a 5-year period. ACE inhibitors have been shown to decrease LV volume in some studies. However, the benefits of ACE inhibitor therapy were seen only when blood pressure was effectively lowered.

(2) In patients with significant aortic root dilation as a result of cystic medial necrosis or related conditions, treatment with a β-blocker should be considered to slow the rate at which the aortic root enlarges. This has been proved to be beneficial in Marfan's syndrome and is also indicated in patients with bicuspid AV and dilated aortic roots without moderate or severe AR. Angiotensin receptor blockers have also been associated with reduction in progression of aortic disease and should be considered in patients with Marfan-related syndromes. When aortic root dilation is larger than 5 cm in severe AR (lower in Marfan's syndrome), aortic valve surgery and root replacement are indicated.

b. Acute AR

(1) The goal of **medical therapy** in acute AR is hemodynamic stabilization before proceeding with surgical correction. For patients presenting with cardiogenic shock, intravenous vasodilators are used to reduce the afterload stress on the left ventricle, to lower LVEDP, and to augment forward cardiac output. In severe cases, intravenous inotropic agents may be required for temporary hemodynamic support. β-Blockers may be used with caution when acute AR is caused by an aortic dissection. β-Blockers help reduce arterial dP/dt, which reflects the transmission of force from LV ejection to the arterial wall. Although this is an essential component of the treatment of acute aortic dissection, β-blockers increase the length of diastole by slowing the heart rate, which can exacerbate acute AR and contribute to cardiovascular collapse.

(2) A **surgical evaluation** should be performed immediately for a patient with AR caused by aortic dissection or chest trauma. The goal of medical therapy in this setting is to maximize forward cardiac output and minimize propagation of aortic dissection if present.

(3) If acute AR is associated with **endocarditis**, antibiotic therapy should be instituted as soon as all culture specimens are obtained.

2. Percutaneous therapy. ***Insertion of an intraaortic balloon counterpulsation device in patients with more than moderate AR or in the presence of aortic dissection is contraindicated.*** Patients with combined AS and AR are poor candidates for PABV because the degree of AR is likely to increase after the procedure.

3. Surgical therapy

a. Chronic AR. The ACC/AHA guidelines on the indications for AVR in patients with chronic AR are given in Table 15.9.

(1) **Symptomatic patients.** The updated ACC/AHA guidelines state that AVR is recommended for symptomatic patients with severe AR regardless of the ejection fraction.

(2) The indications for AVR in **asymptomatic patients** remain controversial. AVR is recommended when patients with chronic severe AR are undergoing any other open heart surgery. Asymptomatic patients with chronic, severe AR and LV systolic dysfunction (ejection fraction < 50%) are at high risk for the development of symptomatic heart failure within 2 to 3 years and, therefore, should be considered for elective surgical intervention. Asymptomatic patients with normal LV systolic function at rest and evidence of severe LV dilation (LV end-diastolic dimension > 75 mm and end-systolic dimension > 55 mm) have an increased risk of sudden cardiac death. Their prognosis after AVR, however, is excellent, and they should be referred for valve replacement. When patients with severe LV dilation develop symptoms or LV systolic dysfunction, the perioperative mortality rate increases significantly. AVR is not recommended in asymptomatic patients with normal systolic function at rest and normal or mildly abnormal LV dimensions (end-diastolic

TABLE 15.9 Indications for Aortic Valve Replacement in Severe Aortic Regurgitation

Indication	Class
Symptomatic patients with severe AR irrespective of LV systolic function	I
Asymptomatic patients with chronic, severe AR and LV systolic dysfunction (EF < 50%) at rest	I
Patients with chronic, severe AR undergoing coronary artery bypass surgery or surgery on the aorta or other heart valves	I
Asymptomatic patients with severe AR and EF > 50%, but with severe LV dilation (EDD > 75 mm or ESD > 55 mm[a])	IIa
Patients with moderate AS while undergoing surgery on the ascending aorta or coronary artery bypass grafting surgery	IIb
Asymptomatic patients with severe AR and normal LV systolic function (EF > 50%) when the EDD > 70 mm or ESD > 50 mm, when there is evidence of progressive LV dilation[a], declining exercise tolerance or abnormal hemodynamic responses to exercise	IIb
AVR not indicated for asymptomatic patients with mild, moderate, or severe AR and normal LV systolic function at rest (EF > 50%) and when degree of dilation is not severe (EDD < 70 mm and ESD < 50 mm)	III

AR, aortic regurgitation; LV, left ventricular; EF, ejection fraction; EDD, end-diastolic dimension; ESD, end-systolic dimension; AS, aortic stenosis.

[a]Consider lower threshold values for patients of small stature of either gender.

From Bonow RO, Carabello B, Chatterjee K, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: an executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 guidelines for the management of patients with valvular heart disease). *J Am Coll Cardiol.* 2006;48:598–675, with permission from Elsevier.

dimension < 70 mm and end-systolic dimension < 50 mm). However, in practice, few physicians wait until the LV end-diastolic dimension is 75 mm or the end-systolic dimension is 55 mm to consider surgical intervention even if the patient remains asymptomatic. Most physicians weigh up the benefit and risk to the individual patient and err on sending the asymptomatic patient to surgery at a lower end-systolic dimension (usually 50 mm) and may opt to intervene even earlier in patients of smaller body size and height.

(3) The **surgical alternatives** are discussed in **Section** I. **Many patients with prolapse of bicuspid valve as the cause of AR may be candidates for surgical repair of the aortic valve.** Some patients with leaflet perforation caused by infectious endocarditis may be candidates for repair in which a pericardial patch is sewn over the defect.

(4) Postoperatively, patients with severe AR may show initial worsening in LV function despite relative normalization of LV size. This is likely due to the hemodynamic changes produced by eradicating the regurgitation. Slow improvement with normalization or at least stabilization of function at about 6 months is common in these patients. Afterload reduction is indicated postoperatively in patients with impaired LV systolic function at least until there is normalization of LV systolic function.

4. **Follow-up care.** Patients with chronic AR should be observed closely for the development of LV systolic dysfunction. Follow-up evaluation is typically conducted with serial echocardiography. When signs of LV systolic dysfunction manifest, consideration should be given to surgical therapy, even if the patient has no symptoms. Routine postoperative care is appropriate after AVR or repair is completed.
5. **Key suggestions**
   a. Acute, severe AR is usually a surgical emergency. Signs of congestive heart failure and mitral valve preclosure are ominous in acute AR.
   b. Valve replacement can be performed without infection of the prosthesis in active endocarditis, even when antibiotics have only recently been started. An aortic valve homograft is the preferred prosthesis in the setting of endocarditis.
   c. Aortic dissection should be suspected in any patient with chest pain and AR.
   d. If LV systolic dysfunction is present for < 18 months, LV function is likely to improve postoperatively.
   e. Heart rate is usually normal until late in the course of disease, when a low effective stroke volume is compensated with tachycardia to maintain cardiac output.
   f. Rapid atrial or ventricular pacing may be used as a temporary measure to manage acute AR caused by endocarditis or trauma to improve cardiac output. The diastolic-filling phase is shorter at higher heart rates; therefore, there is less time for valvular regurgitation.

Mitral Valve Disease

I. INTRODUCTION

A. The **mitral valvular apparatus** consists of the anterior and posterior leaflets, the mitral annulus, the chordae tendineae, and the papillary muscles (PMs).

1. Normal function of the apparatus brings both leaflets together in systole, creating the coaptation zone.

2. The anterior portion of the mitral annulus is in continuity with the fibrous skeleton of the heart, making it less prone to dilation than the posterior annulus.

3. The coaptation line of the anterior and posterior leaflets is located in the posterior one-third of the valve orifice.

4. The middle scallop of the posterior leaflet is designated P_2, with the lateral scallop designated P_1 and medial scallop designated P_3. The corresponding areas of the anterior leaflet are designated A_1, A_2, and A_3.

5. The mitral valve leaflets are attached via the chordae tendineae to the PMs, which are part of the left ventricle.

B. Mitral regurgitation (MR) can occur as a result of malfunction of any of these components.

C. Mitral valve prolapse (MVP) exists when one or both mitral leaflets extend beyond the plane of the mitral valve annulus into the left atrium during systole.

D. Mitral stenosis (MS) is usually valvular and is caused more rarely by the fusion of subvalvular components.

II. MITRAL REGURGITATION

A. Clinical presentation

1. Signs and symptoms

a. With **acute, severe de novo MR**, an abrupt rise in pulmonary capillary wedge pressure (PCWP) causes pulmonary edema. The symptoms include rest dyspnea, orthopnea, and possibly signs of diminished forward flow, including cardiogenic shock.

b. Chronic MR is usually **asymptomatic** for years. The most common presentation is an asymptomatic murmur. **When symptoms develop**, exercise intolerance and exertional dyspnea usually occur first. Orthopnea and paroxysmal nocturnal dyspnea may develop as MR progresses. Fatigue is caused by diminished forward cardiac output. With the development of left ventricular (LV) dysfunction, further symptoms of congestive heart failure (CHF) are manifest. **Long-standing severe MR** may cause **pulmonary hypertension**, with symptoms of right ventricular (RV) failure. Atrial fibrillation commonly occurs as a consequence of left atrial (LA) dilation.

2. Physical findings

a. Inspection and palpation. When LV function is preserved, carotid upstrokes are sharp, and the cardiac apical impulse is brisk and hyperdynamic. An early diastolic LV filling wave may be palpable because of the

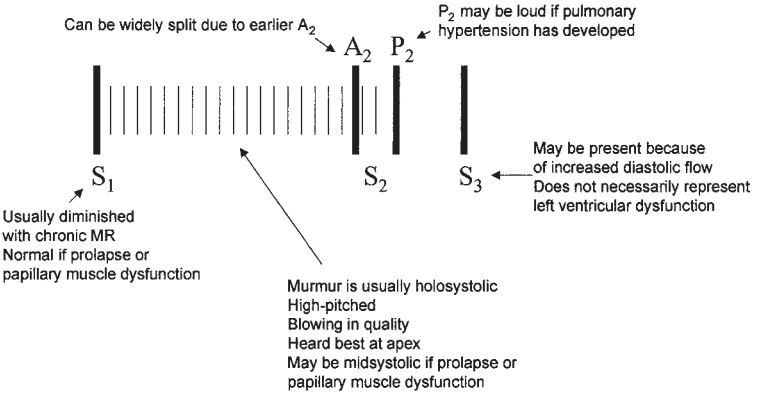

FIGURE 16.1 Auscultatory findings in mitral regurgitation.

large volume of blood traversing from the left atrium to the left ventricle. A late systolic thrust may be present in the parasternal location because of systolic expansion of the left atrium (which may be difficult to differentiate from an RV lift). With the development of LV dilation, the apical impulse is displaced laterally. An RV heave and a palpable P_2 are present if pulmonary hypertension has developed. An elevated jugular venous pressure, hepatomegaly, ascites, and peripheral edema indicate secondary RV dysfunction.

b. Auscultation. The main auscultatory findings are shown in Figure 16.1. A loud S_4 (not illustrated) can be heard sometimes, particularly with acute MR. In acute, severe MR, the systolic driving pressure across the mitral valve is reduced due to a high LA pressure and, as a result, the murmur is short and relatively soft. If the LA pressure is markedly elevated, the murmur of acute MR may be inaudible. With decompensated systolic heart failure, fine inspiratory pulmonary crackles may be evident.

3. The **differential diagnosis of holosystolic murmurs** includes MR, tricuspid regurgitation, and ventricular septal defect (VSD). All are high pitched, but the murmur of a VSD is often harsh in quality, unlike the blowing murmurs of MR and tricuspid regurgitation.
   - **a.** The murmur of **MR** is best heard in the apical position and often radiates to the axilla (although possibly to the base with anteriorly directed jets); those of tricuspid regurgitation and VSD typically do not. The murmur of posteriorly directed MR radiates to the back.
   - **b.** Tricuspid regurgitation is best heard at the left lower sternal border and radiates to the right of the sternum and left midclavicular line. Like all right-sided murmurs, tricuspid regurgitation is accentuated by inspiration.
   - **c.** A **VSD** murmur is heard at the left sternal border and often radiates throughout the precordium.

B. Etiology and pathophysiology. MR is more commonly myxomatous or ischemic, rather than rheumatic, in etiology. The causes of MR are summarized in Table 16.1.

1. In **acute MR**, the regurgitant volume that returns from the left atrium causes a **sudden increase in LV end-diastolic volume.** The left ventricle compensates for this by means of the Frank-Starling mechanism: increased sarcomere length (preload) enhances LV contraction (inotropy). This occurs at the cost of

TABLE 16.1 Causes of Mitral Regurgitation

Leaflet abnormalities
Myxomatous degeneration of leaflets with excessive motion (most common)
Rheumatic disease: scarring and contraction lead to the loss of leaflet tissue
Endocarditis: can cause leaflet perforations and retraction in the healing phase
Aneurysms: usually from aortic valve endocarditis; aortic insufficiency produces jet lesion on the mitral valve
Congenital:
- Cleft mitral valve: isolated or with ostium primum atrial septal defect
- Double-orifice mitral valve

Hypertrophic cardiomyopathy: systolic anterior motion of the mitral valve

Mitral annular abnormalities
Annular dilation
- From left ventricular dilation: dilated cardiomyopathy, ischemic disease, hypertension
- Normal 10 cm in circumference
- With sufficient dilation, loss of adequate leaflet coaptation
- Tethering of leaflet and chordae can occur and produce relative restriction of leaflet motion

Mitral annular calcification
- Degenerative disorder, most commonly seen in the elderly
- Accelerated by hypertension or diabetes
- Also seen in renal failure with dystrophic calcification
- Also seen with rheumatic heart disease
- Marfan syndrome and Hurler syndrome
- Mitral regurgitation results from immobility of the annulus and loss of sphincter activity

Chordal abnormalities
Chordal rupture (most severe form is flail leaflet) results in loss of leaflet support usually with myxomatous degeneration
Rheumatic heart disease (chordal fibrosis and calcification)

Papillary muscle abnormalities
Rupture with myocardial infarction
- Complete rupture typically not survived
- Partial rupture more typically encountered

Dysfunctional papillary muscle
- Ischemia
  - Posteromedial papillary muscle, single blood supply through posterior descending artery
  - Anterolateral papillary muscle, supplied by left anterior descending artery and left circumflex artery

Infiltrative processes: amyloid and sarcoid
Congenital: malposition, parachute mitral valve

increasing LV filling pressure and may cause symptoms of pulmonary congestion. LV wall stress (afterload) is reduced because blood is ejected into the lower pressure left atrium as well as into the systemic circulation. Increased inotropy and reduced afterload cause more complete LV emptying and hyperdynamic function. Forward cardiac output declines, however, because much of the flow is directed to the left atrium. If the acute hemodynamic insult is tolerated, the patient's condition **may progress to a chronic compensated state**.

2. In **chronic compensated MR**, there is **dilation of the left ventricle with eccentric hypertrophy**.
   a. Wall stress is normalized with the development of hypertrophy. Afterload reduction by the low-resistance left atrium is not as significant as it is in the acute phase. Preload remains elevated by the same mechanism as in acute MR. LA dilation helps to accommodate the increased preload at lower filling pressures. LV function is not as hyperdynamic as in the acute state but is in the high-normal range.
   b. Patients may stay in this asymptomatic or minimally symptomatic phase for years; however, **contractile dysfunction may develop insidiously** during this phase. Increased preload, normal or decreased afterload, and increased sympathetically mediated contractility all continue to augment the ejection fraction (EF). However, as the regurgitant volume ejected back into the left atrium diminishes the actual forward stroke volume (SV), the EF may overrepresent cardiac output.
3. In **chronic decompensated MR**, there is LV dysfunction along with progressive enlargement of the LV chamber with increased wall stress. LV dysfunction and enlargement increase the severity of MR, further contributing to the cycle of deterioration. **Irreversible LV contractile dysfunction** may be present by the time overt symptoms develop and this confers higher rates of postoperative heart failure and increased mortality.

C. Laboratory examination

1. The **electrocardiographic** findings are **nonspecific**. The principal features are LA enlargement and atrial fibrillation. LV hypertrophy and RV hypertrophy may also be seen in patients with severe MR.
2. Chest radiography. Cardiomegaly with LA and LV enlargement may be seen in chronic MR. Interstitial edema, manifest as Kerley B lines, followed by alveolar edema may develop in acute cases or with progressive LV failure. Calcification of the mitral annulus may be visualized as a C-shaped opacity in the lateral projection.

D. Diagnostic testing

1. Echocardiography plays a pivotal role in the evaluation of MR. It is useful in **diagnosing MR and in determining its severity and cause**. MR **severity is graded semiquantitatively as follows**: 1+ for mild, 2+ for moderate, 3+ for moderately severe, and 4+ for severe regurgitation. Increasingly, **MR is quantified where feasible**. This is accomplished most often using the proximal convergence method (see below). Quantification provides prognostically powerful information that is less affected by the ongoing loading conditions.

   The American College of Cardiology/American Heart Association (ACC/AHA) class I recommendation is for the use of Doppler echocardiography to determine the mechanism and severity of MR, to assess the LA and LV size and function over time, to assess the pulmonary artery (PA) pressures, and to reevaluate periodically if more than mild, and after mitral valve surgery. The current ACC/AHA classification of MR severity by Doppler echocardiography is summarized in Table 16.2.
   a. Color Doppler echocardiography allows the diagnosis of MR by means of visualization of the regurgitant jet or jets entering the left atrium and allows the assessment of severity.
      (1) Jet length and area are used in this assessment. These measurements are **reliable with central jets**, but underestimation of MR may occur with eccentric jets. Because a jet directed against the atrial wall appears smaller than a free jet of the same regurgitant volume (Coanda effect), it is common practice to upgrade the estimated severity of MR by at least one grade in this situation. The direction of the MR jet can also aid in assessing the

TABLE 16.2 Assessment of Severity of Mitral Regurgitation

	Mild	Moderate	Severe[a]
Qualitative			
Angiographic grade	1+	2+	3–4+
Color Doppler jet area	Small, central jet (< 4 cm^2 or < 20% LA area)	Signs of MR > mild present, but no criteria for severe MR	Vena contracta width > 0.7 cm with large central MR jet (area > 40% of LA area) or with a wall-impinging jet of any size
Doppler vena contracta width (cm)	< 0.3	0.3–0.69	≥0.70
Quantitative (cath or echo)			
Regurgitant volume (mL/beat)	< 30	30–59	≥60
Regurgitant fraction (%)	< 30	30–49	≥50
Regurgitant orifice area (cm^2)	< 0.20	0.2–0.39	≥0.40

[a]In severe MR, evidence of LA and LV dilation is essential.

MR, mitral regurgitation; LA, left atrium; LV, left ventricle.

Adapted from 2006 Valve Disease ACC/AHA Guidelines.

cause of MR (Table 16.3). Regurgitation caused by prolapse or flail (excessive leaflet motion) results in a jet direction opposite to the affected leaflet (i.e., posterior jet with anterior leaflet prolapse). MR caused by leaflet restriction (rheumatic and ischemic) is directed toward the affected leaflet.

(a) Caveats

i. MR is assessed with **transesophageal echocardiography (TEE)**. Patients often receive sedation before TEE, and the sedation may reduce systemic blood pressure (afterload). This could make the MR appear less severe than it is under normal physiologic circumstances. This effect of sedation may be mitigated to some extent by increasing the afterload by handgrip or by the cautious administration of phenylephrine.

ii. In the evaluation of MR in the **intraoperative setting**, there may be fluctuations in afterload and preload.

(b) Multiple factors, such as hemodynamic considerations, geometric factors (constraint imposed by the LA wall), and instrumentation, may affect color Doppler measurements. This has led to the development of other measurements to quantify MR.

(2) The width of the vena contracta, which is the narrowest portion of the proximal regurgitant jet downstream from the orifice, is a **reliable indicator of the severity of MR**. A width **≥0.70 cm suggests severe MR**. High-resolution and zoom images must be used for an accurate

TABLE 16.3 Mechanisms, Direction of Color Jet, and Surgical Management of Mitral Regurgitation

Jet direction	Leaflet motion	Likely cause	Surgical method
Anterior	Excessive	Posterior leaflet prolapse	Quadrilateral resection Annuloplasty Chordal shortening Shortening of papillary muscle
	Restricted	Anterior leaflet restriction	Debridement
Posterior	Excessive	Anterior leaflet prolapse	Chordal transfer or shortening
		Posterior leaflet resection to move coaptation apically	
	Restricted	Posterior leaflet restriction	Debridement, annuloplasty
	Normal	Ventricular dilation	Annuloplasty
Central	Excessive	Bileaflet prolapse	Resection, chordal transfer
	Restricted	Bileaflet restriction	Debridement
	Normal	Ventricular dilation	Annuloplasty
Commissural	Papillary muscle dysfunction		Reattach or fold papillary muscle
	Eccentric	Perforation or cleft	Pericardial patch

From Stewart WJ. Intraoperative echocardiography. In: Topol EJ, ed. *Textbook of Cardiovascular Medicine.* Philadelphia, PA: Lippincott–Raven Publishers; 1998, with permission.

assessment of the vena contracta or else TEE may be needed. There is some tendency for overestimation of the width of the vena contracta because of limited lateral resolution.

b. Pulsed-wave Doppler echocardiography of pulmonary venous flow may be useful in the assessment of the severity of MR (Fig. 16.2). Sampling of the pulmonary veins results in three distinct waves: a systolic antegrade wave, a smaller diastolic antegrade wave, and a small negative wave that represents atrial reversal during atrial contraction. With increasing MR, there is a progressive decrease in the systolic wave of pulmonary inflow with eventual reversal. **Blunting of the systolic component** of pulmonary venous flow in the presence of normal LV function suggests at least moderately severe MR. **Systolic flow reversal** suggests severe MR. Blunted pulmonary venous flow is a less reliable indicator of substantial MR in the setting of atrial fibrillation or severe LV dysfunction, since these conditions also can cause systolic blunting.

c. **Pulsed-wave Doppler echocardiography of mitral inflow.** SV across the regurgitant mitral valve can be estimated and compared with the SV derived from pulsed-wave Doppler imaging across a competent valve (such as the aortic or pulmonary valve). The excess flow at the mitral valve over that

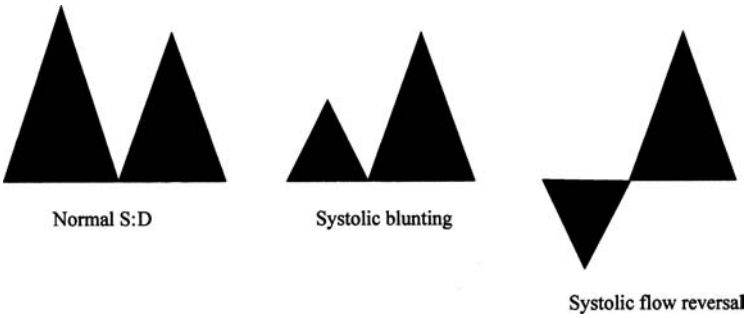

FIGURE 16.2 Patterns of pulmonary venous flow. *First triangle* in each panel represents flow during systole. *Second triangle* represents flow during diastole. The three potential patterns are displayed: normal flow ratio, blunted systolic flow, and reversed systolic flow.

derived at the aortic valve is **the regurgitant volume**. These methods are both tedious and technically difficult.

d. The **proximal isovelocity surface area (PISA)** or flow convergence method provides a quantitative assessment of MR (see Fig. 16.3 and Chapter 67). Peak mitral flow rate is derived as follows:

$$QFC = 2\pi r^2 V$$

where r is the radius of the shell and V is the aliasing velocity at that shell. **Regurgitant orifice area (ROA)**, a relatively load-independent measure of regurgitation, is derived from peak flow rate by dividing this by peak flow velocity (maximal MR continuous-wave velocity, ***Vmr***):

$$ROA = 2\ \pi\pi r^2\ V/\ Vmr$$

The **regurgitant volume** (RV) may be further calculated by the equation ROA × VTI*mr*, where VTI*mr* is the velocity–time integral of the regurgitant jet.

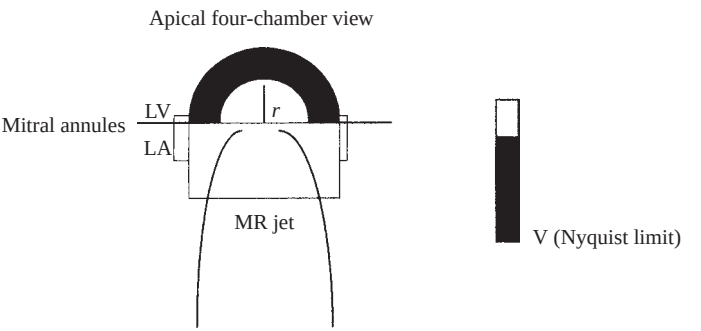

FIGURE 16.3 The proximal isovelocity surface area method for determining severity of mitral regurgitation (MR). LV, left ventricle; LA, left atrium.

If the forward SV is known, then the **regurgitant fraction** (RF%) may be derived as follows:

$$RF = RV/RV + SV$$

SV may be estimated in the LV outflow tract as area × VTI, as performed in the continuity equation (see Chapter 15).

ROA has been shown to be prognostically powerful in MR of ischemic or degenerative origin. **An ROA of 0.4 cm^2** or greater is indicative of severe MR.

(1) Simplified proximal convergence method. The preceding calculation may be simplified to allow the ROA to be estimated with only one measurement. Using this method, MR velocity is assumed to be 5 m/s and the aliasing velocity is set at 40 cm/s. The ROA may be calculated as $r^2/2$. **Higher ROA indicates an increased severity of MR.**

(2) Inaccuracies in using proximal convergence method occur when the orifice is nonspherical, multiple jets are present, or the flow convergence zone is constrained as occurs with eccentric jets. The latter situation occurs with a flail leaflet, as regurgitant flow and ROA are typically overestimated by the use of the PISA method; accuracy may be improved by the use of angle-correction formulas.

2. Cardiac catheterization

a. The **amplitude of the v waves** on hemodynamic tracings (which are a reflection of LA filling from the pulmonary veins during ventricular systole) can provide clues to the severity of MR, particularly in acute MR.

(1) Amplitudes of *v* wave more than two to three times mean LA pressure suggest severe MR. However, in slowly developing MR, an abnormal *v* wave may not be seen. The *v* waves are also diminished by afterload reduction. The **absence of v waves does not exclude severe MR.**

(2) Other conditions that may produce prominent *v* waves are LV dysfunction with a dilated noncompliant left atrium, postinfarction VSD, and other situations in which there is increased pulmonary blood flow.

b. Left ventriculography allows the visual assessment of the severity of MR. It is affected by multiple factors such as the adequacy of the contrast injection to fill the ventricle, the placement of the catheter, and ventricular arrhythmia during injection. The grading system is as follows:

1. **1+ (mild):** clears with each beat; entire left atrium is never opacified.
2. **2+ (moderate):** does not clear with a single beat; may faintly opacify the entire left atrium.
3. **3+ (moderate to severe):** fills entire left atrium over 2 or 3 beats; complete opacification of the left atrium, equal in intensity to the left ventricle.
4. **4+ (severe):** complete opacification of the left atrium in 1 beat; contrast material refluxes into the pulmonary veins.

c. Coronary angiography is useful to detect **concomitant coronary artery disease** (CAD) in these patients. Those being considered for surgery to correct MR undergo coronary angiography, even in the absence of symptoms, if they are older than 50 years or have multiple risk factors.

E. Therapy. An understanding of the pathophysiologic mechanism of MR is essential to management.

1. Acute MR

a. Medical therapy. If there is adequate mean arterial pressure, pharmacologic therapy with **afterload reducing agents** may reduce the acute MR. Intravenous nitroprusside and nitroglycerin may reduce pulmonary pressures and maximize forward flow. If surgery is not immediately indicated a switch to oral agents may be made. Angiotensin-converting enzyme (ACE) inhibitors

(ACE-I) and direct-acting vasodilators (such as hydralazine) help maximize forward output and reduce regurgitant fraction.

b. Percutaneous therapy. The large sudden volume overload on an left ventricle that is not dilated or hypertrophied causes symptoms of pulmonary congestion and even cardiogenic shock. For such patients with acute hemodynamically significant MR, especially from postinfarction PM rupture, placement of an intraaortic balloon pump (IABP) may serve as a temporary stabilizing measure until surgical repair can be undertaken.

c. Surgical therapy. Patients with acute, severe MR usually require urgent surgical intervention.

2 Chronic MR

a. Choosing the appropriate therapy (see Table 16.4 for a summary of the current ACC/AHA guidelines)

(1) Most patients who have **moderately severe to severe MR** and are **symptomatic** should be considered for elective surgical treatment. Decisions need to be individualized based on the age of the patient, the likelihood of valve repair, comorbidities, LV function, and the likelihood that surgical intervention will improve symptoms and/or survival. Generally, **intervention for symptoms is indicated for severe MR if the cause of the MR is primary to the valve** (i.e., prolapse, rheumatic, or congenital in origin). When the **valve lesion is secondary to ventricular dysfunction,** either from ischemic heart disease or from dilated cardiomyopathy, **aggressive medical management of heart failure** (see subsequent text) is indicated first.

(3) In **severe MR due to dilated cardiomyopathy associated with severe symptoms** and refractory to medical management and cardiac resynchronization therapy (CRT) where indicated, mitral valve repair may lead to symptomatic improvement, but a survival benefit has not yet been demonstrated.

(4) Management of patients with **minimal or no symptoms but severe MR** is more complex. **The key is to identify patients before contractile dysfunction of the left ventricle becomes irreversible.** Watchful waiting until serious symptoms develop carries a risk for the development of severe LV dysfunction and a poor prognosis. The feasibility of mitral valve repair with improved postoperative survival and EF (see later) has been another incentive in the push for earlier surgical intervention. If the valve repair is not feasible, one may choose to wait longer before proceeding to surgical treatment. The 2006 valve guidelines **lowered the threshold to intervene in asymptomatic patients with repairable valves** when repair is performed in an experienced center where the likelihood of repair exceeds 90% (Table 16.4).

b. Timing of surgery. A variety of clinical, echocardiographic, and invasively derived values appear to be predictive of the development of postoperative LV dysfunction, decompensated heart failure, and death among patients with significant but asymptomatic MR. The timing of mitral valve surgery is a **decision that must be individualized** and depends on several variables, including clinical signs and symptoms, echocardiographic findings, catheterization data, hemodynamic data, operative risk, and repairability of the mitral valve. Generally, the variables to be considered in patients whose MR is asymptomatic are (a) LV size and function; (b) exercise capacity and LV size and function at peak exercise; (c) repairability of the valve; (d) severity of MR, including the presence of flail leaflet; (e) pulmonary artery pressures; (f) atrial fibrillation; and (g) age and other comorbidities.

TABLE 16.4 Indications for Mitral Valve Surgery in Mitral Regurgitation

Class I

- **(a)** MV surgery is recommended for the symptomatic patient with acute severe MR
- **(b)** MV surgery is of benefit for patients with chronic severe MR and NYHA functional class II, III, or IV symptoms in the absence of severe LV dysfunction (severe LV dysfunction is defined as ejection fraction < 0.30) and/or end-systolic dimension > 55 mm
- **(c)** MV surgery is of benefit for asymptomatic patients with chronic severe MR and mild to moderate LV dysfunction, ejection fraction 0.30–0.60, and/or end-systolic dimension ≥ 40 mm
- **(d)** MV repair is indicated over MV replacement in most patients with severe chronic MR who require surgery, and patients should be referred to surgical centers experienced in MV repair

Class IIa

- **(a)** MV repair is reasonable in experienced surgical centers for asymptomatic patients with chronic severe MR with preserved LV function (ejection fraction > 0.60 and end-systolic dimension < 40 mm) in whom the likelihood of successful repair without residual MR is > 90%
- **(b)** MV surgery is reasonable for asymptomatic patients with chronic severe MR, preserved LV function, and new-onset atrial fibrillation.
- **(c)** MV surgery is reasonable for asymptomatic patients with chronic severe MR, preserved LV function, and pulmonary hypertension (pulmonary artery, systolic pressure > 50 mm Hg at rest or > 60 mm Hg with exercise)
- **(d)** MV surgery is reasonable for patients with chronic severe MR due to a primary abnormality of the mitral apparatus and NYHA functional class III–IV symptoms and severe LV dysfunction (ejection fraction < 0.30 and/or end-systolic dimension > 55 mm) in whom MV repair is highly likely

Class IIb

MV repair may be considered for patients with chronic severe secondary MR due to severe LV dysfunction (ejection fraction < 0.30) who have persistent NYHA functional class III–IV symptoms despite optimal therapy for heart failure, including biventricular pacing

Class III

- **(a)** MV surgery is not indicated for asymptomatic patients with MR and preserved LV function (ejection fraction > 0.60 and end-systolic dimension < 40 mm) in whom significant doubt about the feasibility of repair exists
- **(b)** Isolated MV surgery is not indicated for patients with mild or moderate MR

Adapted from 2006 Valve Disease ACC/AHA Valve Disease Guidelines.

(1) LV size and function. As noted previously, contractile impairment is often occult in severe MR when conventional indices of LV function are used. Elastance measured at the time of cardiac catheterization is the best load-independent measure of true contractile function in MR. However, as it requires the construction of a series of pressure–volume loops for its calculation, it is rarely performed outside research laboratories. Fortunately, conventional indices of LV size and function do

provide useful information in MR. Newer noninvasive techniques, such as two-dimensional (2D) strain imaging, are of interest because of their ability to detect subtle changes in LV function that precede reductions in EF. **In severe primary MR with preserved contractile function, left ventricular ejection fraction (LVEF) should be in the high-normal range. Studies have indicated that once the LVEF is < 60%, the likelihood of impaired survival and permanent LV dysfunction postoperatively is high**. Therefore, consideration should be given to surgical intervention before the LVEF drops to below 60%. Increased LV size and volume in end systole (more load-independent than end diastole) is also an indicator of increased likelihood of impaired survival and LV dysfunction postoperatively. When **LV end-systolic diameter is > 4.0 cm, surgical intervention should be considered**.

(2) We have found that **exercise echocardiography** is very helpful in determining the likelihood of latent LV contractile dysfunction. **The ability of the left ventricle to cope with exercise is an indication of its contractile reserve**. In addition, **poor functional capacity** may indicate an adaptive response to MR (the patient was not truly asymptomatic) and may influence the decision to proceed with surgical treatment. We have found that a **failure to *increase* LVEF, or for end-systolic volume to *decrease* with stress, is predictive of postoperative LV dysfunction** and is a superior predictor of this eventuality than resting LVEF. In patients with severe asymptomatic MR, we perform stress echocardiography at 6-month intervals and recommend mitral valve surgery once end-systolic volume fails to decrease significantly at peak exercise or if LVEF fails to increase. This is particularly helpful in patients who wish to postpone surgical intervention as long as possible.

(3) The **feasibility of repair** depends on the cause of MR. This can be determined during the preoperative evaluation by echocardiography. **Repair in an experienced center is usually likely in MVP unless chordae to both leaflets are severed, severe damage from endocarditis has occurred, or there is extensive leaflet calcification**. Repair is usually feasible for a cleft valve and in less extreme forms of endocarditis such as leaflet perforation without chordal disruption, as well as in many cases of secondary MR (ischemic or dilated cardiomyopathy). Repair is more difficult to achieve in rheumatic involvement and when the valve leaflets or chordae are severely disrupted from any cause. **The threshold to intervene surgically is lower if repair appears feasible because of the lower surgical and long-term mortality and morbidity associated with repair compared with replacement**.

(4) The more severe the MR, the greater the volume load on the left ventricle usually, and the more likely that LV dysfunction will develop. One caveat here is that MR is not always holosystolic. Occasionally, apparently severe MR is seen without evidence of significant LV enlargement because the MR is occurring only in the latter part of systole.

The threshold to intervene surgically is lower as MR severity increases. In situations where MR severity is in doubt, a TEE should be performed and the quantitative assessment used as described previously. A flail leaflet usually (but not always) implies severe MR. A retrospective study suggested that earlier surgical intervention was associated with better long-term survival in patients with a flail leaflet, even if the condition was asymptomatic, with flail being considered a surrogate for severe MR. More recent quantitative studies suggest that once ROA is ≥ 0.4 cm^2, survival is better in those treated surgically, even in the absence of symptoms.

(5) Pulmonary pressures > 50 mm Hg at rest or > 60 mm Hg at peak exercise in the absence of another likely cause are an indication of severe MR and impaired survival and these **are considered ACC/AHA class IIa indications for surgical intervention**. These can be assessed noninvasively from the tricuspid regurgitant velocity at stress echocardiography.

(6) The occurrence of **atrial fibrillation** or flutter in the setting of severe MR is considered an indication (IIa) for surgical intervention. A concomitant maze or more usually now a modified maze procedure (pulmonary vein and great vein isolation) may be performed with mitral valve repair, especially if atrial fibrillation has become persistent or frequent.

(7) Age and other comorbidities. Patients > 75 years, those with concomitant CAD, or those with renal dysfunction have worse outcomes after surgical treatment. Patients with ischemic MR have a worse prognosis than those with regurgitation from other causes.

c. Medical therapy

(1) The role of medical therapy for **asymptomatic, chronic MR caused by primary valve disease** is not well established. There is no evidence that pharmacologic agents delay progression of the disease or prevent ventricular dysfunction. Patients with severe MR should be evaluated semiannually with echocardiography and stress echocardiography, if indicated. Patients with moderate MR should be evaluated annually.

(a) The success of afterload reducers in acute MR has led to trials of vasodilators, such as **ACE-I and hydralazine**, in chronic MR. However, existing small trials have been largely negative. As a result, the ACC/AHA and European Society of Cardiology guidelines recommend against the use of pharmacological vasodilatation in chronic MR with preserved EF, although this is not necessarily reflected in common practice.

(b) Sympathetic overstimulation appears to be a key element of progression to LV failure in MR, and there is limited evidence for the experimental use of β-blockers in MR but no clinical evidence of utility of postponement of surgical intervention.

(c) MR secondary to LV dysfunction is managed with standard heart failure therapy, including ACE-I and β-blockers.

(d) Diuretics and nitrates have a role in the management of pulmonary congestion.

(e) Ventricular rate-controlling agents and antiarrhythmics are used for atrial fibrillation. **Digitalis and β-blockers** are the mainstay of therapy for rate control. In severe MR with atrial fibrillation, maintenance of sinus rhythm is unlikely if the regurgitation remains uncorrected.

(2) **In accordance with recent AHA guidelines**, endocarditis prophylaxis is not routinely indicated in patients with MR. These new guidelines recommend that prophylaxis be used only in patients with underlying cardiac conditions associated with the highest adverse outcome from infective endocarditis, including prosthetic heart valves or prior repair surgery, previous infective endocarditis, certain classes of congenital heart disease, and in valvulopathy occurring post cardiac transplantation.

d. Surgical therapy

(1) Mitral valve replacement with transection of the subvalvular apparatus was once the only approach used in the surgical management of MR. Postoperative reduction of LV function and decompensated heart failure were common sequelae. Chordal preservation by leaving the subvalvular structures intact has been shown to reduce LV volumes and wall stress postoperatively and is now the technique of choice.

(2) The increasing success of **mitral valve repair** has greatly reduced the morbidity and mortality associated with severe MR. Mitral valve repair almost always involves placement of an undersized annuloplasty ring, which reduces annular diameter, improves leaflet coaptation, and significantly decreases MR. Additional components may include a pericardial patch at the site of leaflet perforation, chordal shortening or transposition, leaflet resection, and sliding valvuloplasty of the posterior leaflet to reposition the coaptation line. Artificial chordae are increasingly used in the repair of anterior leaflet prolapse.

(3) Although no randomized trials have compared repair with replacement, **comparative data suggest better postoperative LV function and survival with repair** (which in part reflects the selection of patients who are able to undergo repair). Long-term risk of thromboembolism and endocarditis is reduced with repair versus replacement, and the need for reoperation is similar. Excellent 20-year outcomes following repair have been reported from multiple large volume centers, with the estimated risk of reoperation approximating 10%.

(4) **Minimally invasive** video-assisted approaches employing hemi-lower sternotomy and right thoracotomy incisions may be options in experienced centers and selected patients. In the latter, cardiopulmonary bypass is usually achieved via femoral artery and vein cannulation. These approaches have the benefit of smaller incisions, resulting in more rapid postoperative recovery but require considerable expertise. Introduction of robotic surgical instrumentation and high-definition three-dimensional (3D) imaging allows mitral valve repair through portlike incisions, with further reduction in procedural invasiveness. **Robotically assisted valve repair** has shown good results in a few centers, although there are currently no data for superior outcomes. Complex surgeries, particularly if they require concomitant coronary artery bypass grafting (CABG) or multivalvular repair, are likely better handled with a standard operative approach at this point. These techniques may enjoy broader application in the future.

(5) **Mitral valve replacement** is indicated when repair is not technically possible. The choice of **mechanical or bioprosthetic** valve replacement depends on weighing the risk of chronic anticoagulation required with mechanical valves, against the reduced longevity of the bioprosthetic valves. Structural degeneration of bioprosthetic mitral valves typically affects 20% to 40% patients at 10 years and over 60% at 15 years.

(6) Intraoperative echocardiography helps in the **assessment of complications** of valve repair or replacement.

- (a) Residual MR is the most common problem after a pump run. If further repair is feasible, a second pump run should be considered to correct residual MR (if 1+ or greater). If further repair is not possible, valve replacement may be needed. A second pump run does not appear to increase in-hospital mortality.
- (b) **Dynamic LV outflow obstruction** is an important potential complication of mitral valve repair. This is now uncommon in experienced centers. It is caused by anterior displacement of mitral leaflet coaptation point when the posterior leaflet is redundant (typically > 1.5 cm in height). The result is systolic motion of the mitral leaflet into the outflow tract, creating a pressure gradient across the outflow tract and the development of MR. This may be apparent immediately after surgery in the operating room, with intraoperative echo or later in the course. It is exacerbated by increased inotropy and small LV size. Many instances resolve with cessation of the use of

sympathomimetic agents and volume repletion. In the operating room, if these efforts fail to correct the condition, more surgery to reduce the height of the posterior mitral leaflet (sliding annuloplasty) or, rarely, mitral valve replacement may be necessary. In the postoperative patient, volume repletion and judicious use of β-blockade are often all that is necessary, although occasionally surgical revision of the repair is needed. The development of a new apical systolic murmur in the patient who has undergone mitral valve repair should prompt an echocardiogram to exclude this complication.

e. Postsurgical follow-up care

(1) Baseline echocardiography should be performed postoperatively. This is ideally scheduled 4 to 6 weeks after the operation, but for the sake of convenience it is often done before hospital discharge (within 3 to 4 days).

(2) MR can recur because of failure of the repair or because of progression of the disease that caused MR. Patients should undergo clinical evaluations at least once a year. **Yearly echocardiography** after the operation to assess for MR and LV function is reasonable.

f. Resynchronization therapy. LV wall motion abnormalities are often the major pathology in secondary (functional) MR, and CRT has demonstrated symptomatic benefit in carefully selected patients.

g. Percutaneous mitral valve repair. Percutaneous mitral valve repair is a developing catheter-based treatment option in which improved coaptation of the mitral leaflets is attempted using an implantable device. Current techniques emulate the existing surgical procedures, with the devices currently under investigation being classified into two functional approaches.

(1) A **clip** can be used to approximate the center of the mitral valve leaflets, thus giving a double-orifice valve in an approach that models the surgical Alfieri edge-to-edge repair. To date, this is the best studied percutaneous option, with the Endovascular Valve Edge-to-Edge Repair Study II recently reporting the 12-month results of 279 patients with 3 to 4+ MR randomized to MitraClip (Abbott Vascular, Menlo Park, CA, USA) versus surgical mitral valve repair/replacement. The primary composite end point for efficacy was freedom from death, from mitral valve surgery, and from 3 or 4+ MR. About 55% of subjects in the percutaneous repair group met the end point at 1 year compared with 73% in the surgery group. All-cause mortality was equivalent in the percutaneous and surgical groups. There were significantly fewer adverse events in the percutaneous group, although significance was lost when blood transfusion was excluded as a complication. Implantation of the MitraClip is currently performed in the United States as part of a continued access registry.

(2) A **flexible ring** can be deployed and tightened in the coronary sinus (CS) in order to effectively reduce the mitral annulus area. Concerns regarding this procedure include the variable relationship between the CS and mitral annulus, as well as the proximity to the circumflex artery. Devices under investigation include two stents deployed into the CS, with the connecting coil bridge being tightened over time called the Monarc (Edwards Lifesciences, Irvine, CA, USA); a fixed length, double-anchor CS device called the Carillon Mitral Contour System (Cardiac Dimensions, Kirkland, WA, USA); and a CS anchor that is attached to the interatrial septum via a cord under tension called the Percutaneous Septal Shortening System (Ample Medical, Foster City, CA, USA).

The clip may be more appropriate for repair of MVP, whereas annular remodeling is felt to be better suited for the repair of functional regurgitation.

III. ISCHEMIC MR (IMR)

A. Clinical presentation. IMR may present either acutely in the setting of active ischemia or infarction or chronically with long-standing CAD. Among patients with CAD, the presence of MR portends a worse prognosis. Acute severe IMR presents with cardiogenic shock and hemodynamic instability, with symptoms and signs consistent with those previously described for acute MR. The clinical presentation of chronic IMR also parallels that of other etiologies of chronic MR; in addition, a history of known CAD or cardiovascular risk factors should be sought.

B. Etiology and pathology

1. Ischemia or infarction may give rise to one or more of the following mechanisms of IMR. Those common in the acute setting include the following:
   a. PM rupture or chordal avulsion;
   b. altered LV geometry, causing PM displacement; and
   c. elongation of the infarcted PM and exaggerated contraction of the noninfarcted PM.
2. Mechanisms common in the chronic IMR setting include
   a. PM necrosis causing leaflet tethering and poor coaptation;
   b. decreased mitral valve closing forces because of LV systolic dysfunction; and
   c. LV cavity dilation causing mitral valve annular dilation.
3. The anterolateral PM receives its blood supply from the left anterior descending and circumflex circulations; the posteromedial PM is supplied by the right coronary or left circumflex artery depending on the coronary dominance.
4. Of note, acute IMR is more frequently a result of geometric changes due to regional LV dysfunction (especially of the inferolateral wall) that induce leaflet tethering and prolapse, rather than ischemia of the PM itself.

C. Laboratory examination and diagnostic testing

1. **Echocardiography.** The most important determinations are the assessment of valvular anatomy, quantification of regurgitation, and evaluation of LV structure and function. Echocardiography can often reveal the mechanism of IMR by evaluating for PM rupture, leaflet restriction, mitral valve tethering, and relevant regional wall motion abnormalities. As previously described, the degree of regurgitation is quantified using color flow and Doppler techniques. Urgent transthoracic echocardiography and/or TEE is the investigation of choice in a patient with acute pulmonary edema where IMR is being considered as an etiology.
2. **Electrocardiogram (ECG).** In acute IMR, ECG is key in evaluating for the presence of active ischemia or infarction. As described above, branches from the left or right coronary systems can supply the PMs. However, it is in the setting of inferior or inferolateral MIs that acute IMR is most commonly seen. In chronic IMR, LA abnormalities, atrial fibrillation, and nonspecific ST-T changes may be seen.
3. **Chest radiography.** In acute IMR, findings of pulmonary edema may be present. Cardiomegaly with LA and LV enlargement may be seen in chronic IMR.
4. **Cardiac catheterization.** Evaluation of the patient with IMR will include angiography to assess the location, extent, and revascularization options of the CAD. In some cases, invasive hemodynamics may provide useful additional data regarding MR severity.

D. Therapy.

1. Intravenous afterload reduction with nitroprusside and nitroglycerin +/– IABP insertion is often required when managing cardiogenic shock secondary to acute IMR. This scenario is associated with a **very poor prognosis**, and surgical intervention with coronary artery bypass and valve repair or replacement is usually the only hope for survival.
2. The medical management of chronic IMR with preserved EF remains controversial, as described above. If LV dysfunction is present, the use of a heart failure medical regimen is essential.

3. Patients with significant IMR will likely require surgery for revascularization and valve repair or replacement. However, studies to date **have not demonstrated any long-term benefit from the addition of valvular surgery to CABG** in this setting. The success rate and durability of valve repair in IMR are significantly lower than those of degenerative mitral valve disease.

IV. MITRAL VALVE PROLAPSE

A. Clinical presentation. Prolapse exists when either or both of the mitral leaflets protrude > 2 mm beyond the annulus into the left atrium during systole, and the coaptation point of the leaflets lies superior to the plane of the annulus. A wide spectrum of pathologic changes and clinical symptoms have been observed, from mild degrees of prolapse diagnosed with echocardiography only to clinically evident severe MR. MVP is the most common cause of MR in the United States. **It affects approximately 2% of the population. Recent studies have suggested an equal prevalence among males and females**. **Males and older patients (age > 45 years) are disproportionately more likely to require surgical intervention** and to develop other major complications such as endocarditis.

1. **Signs and symptoms**
   - **a.** Most patients with MVP have **no symptoms,** and the diagnosis is made by means of routine examination or echocardiography performed for other indications.
   - **b.** Although in the past many symptoms were attributed to MVP, including chest pain, panic attacks, and autonomic instability, more recent studies suggest that these occur no more frequently in patients with MVP than in control populations. Most symptoms associated with adverse prognostic implications occur when significant MR is present.
   - **c.** Arrhythmias are more common with MVP, even in the absence of MR. These include **supraventricular tachyarrhythmias, ventricular tachyarrhythmias, and bradyarrhythmias**. Sudden cardiac death is a rare complication in MVP, occurring in < 2% patients over long-term follow-up. It is more common in the setting of severe MR and/or flail valve leaflet and is likely due to ventricular arrhythmias.
   - **d.** Transient ischemic attack or stroke has been reported in MVP. The most recent studies in this area suggest no excess risk of cerebrovascular events among young patients with MVP.
   - **e.** When prolapse causes MR, symptoms referable to the valvular insufficiency may be present.
2. **Physical findings**
   - **a. Inspection.** There is a higher than expected incidence of **pectus excavatum** among patients with mitral valve. Straight back and scoliosis are also found. Patients often have low body weight and relative hypotension.
   - **b.** The main **auscultatory** findings are shown in Figure 16.4. The **midsystolic click** is the classic finding in prolapse. A systolic murmur is heard if MR is present.
   - **c.** Dynamic changes are elicited by **conditions that decrease LV size** (decreased venous return, increased contractility, or decreased systemic volume), which lead to earlier occurrence of prolapse, an earlier click, and increased duration of the murmur. These conditions include standing, the Valsalva maneuver, dehydration, and exposure to amyl nitrite.
   - **d.** Maneuvers that **increase LV size** by increasing venous return, decreasing contractility, or increasing systemic volume move the click and murmur later into systole. Examples include squatting and infusion of phenylephrine. The presence of a **click that responds to provocative maneuvers is sufficient**

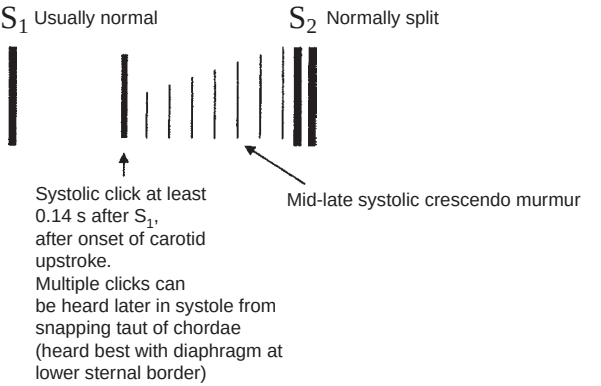

FIGURE 16.4 Auscultatory findings in mitral valve prolapse.

for the diagnosis of prolapse, even if an echocardiogram is not diagnostic (see **Section III.D.1**).

e. The **intensity of the murmur typically decreases with conditions that result in a later click and murmur**. An exception is exposure to amyl nitrite, which also reduces LV systolic pressure and the gradient that drives regurgitant flow. As such, the murmur is of lower intensity, although it occurs earlier in systole.

f. Aortic and pulmonic ejection sounds can produce systolic clicks. These occur earlier in systole than the click of mitral prolapse and may be differentiated on the basis of timing in conjunction with the carotid upstroke. Other causes of midsystolic clicks include septal and free wall aneurysms and mobile tumors such as myxoma. Clicks produced by these conditions do not change with maneuvers that alter LV volume.

B. Etiology and pathology. Prolapse may exist as a result of valvular abnormalities, deemed primary prolapse, or occur in the setting of normal leaflets (secondary prolapse).

1. Primary prolapse results from **myxomatous proliferation of the leaflets**.

Myxomatous mitral valve disease describes thickening of the leaflets and chordae tendineae due to abnormal accumulation of **mucopolysaccharides**, with prominence of the spongiosa layer of the leaflets. Impaired tensile strength is more marked in the chordae than in the leaflets. Chordal elongation results in prolapse and loss of leaflet coaptation and may cause MR. **Thickening of the leaflets ≥5 mm is considered "classic" MVP** and is associated with greater future complications.

a. Within the pathological spectrum of myxomatous mitral valve disease, there are two subtypes of diseases. **Barlow disease** is seen in younger patients, shows greater annular dilation, and has more marked leaflet redundancy and prolapse that may involve multiple segments. Conversely, **fibroelastic deficiency** occurs in older patients, is typically confined to the posterior middle scallop (P_2), and is associated with thinning and rupture of chordae.

b. Primary prolapse appears to have a genetic predisposition. There is a higher prevalence of MVP among family members of those affected, and an **autosomal dominant** mode of inheritance with variable penetrance has been postulated. Recent linkage studies suggest a site on chromosome 16 in some families

with MVP. In addition, MVP is seen as part of disorders with more generalized abnormalities of the connective tissue, such as Marfan syndrome, Ehlers-Danlos syndrome, pseudoxanthoma elasticum, and myotonic dystrophy.

c. Most **complications** of prolapse, particularly severe MR, are associated with primary prolapse. Men in their sixth decade of life represent the most common demographic group with such a presentation.

2. In **secondary prolapse**, there is relatively **normal valvular structure**. A disproportion between leaflet size and LV cavity size produces mechanical forces that may lead to leaflet prolapse. This form of prolapse particularly affects **younger women**. It may also occur with atrial septal defect, hyperthyroidism, emphysema, and hypertrophic cardiomyopathy. Normalization of the relative disproportion between leaflet size and cavity size often occurs with ageing among women, so the incidence decreases with age. **Secondary prolapse is usually of little clinical significance and is not usually associated with significant MR**.

C. Laboratory examination and diagnostic testing

1. **Echocardiography.** M-mode demonstrates late or holosystolic bowing of the mitral valve leaflet 3 mm or more below the C–D line. In 2D echocardiography, prolapse is defined as **>2-mm displacement of one or both mitral leaflets into the left atrium during systole in the parasternal or apical long-axis views**. Caution must be used in making the diagnosis with the apical four-chamber view because normal valve leaflets may appear to prolapse in this view owing to the saddle shape of the mitral annulus. With primary causes of prolapse, increased leaflet thickness (≥5 mm) and redundant leaflets and chordae are seen. Doppler echocardiography is used to assess the presence and severity of MR. Annual echocardiography is advised for those patients with moderate to severe MR.
2. **Electrocardiogram.** If there is severe MR, the findings described earlier are present. Otherwise, the ECG usually is normal or has nonspecific ST-T changes.
3. **Chest radiography.** Pectus excavatum or scoliosis can be present in some cases. If severe MR is present, the typical findings described earlier are seen. Otherwise, the **chest radiograph is usually normal.**

D. Therapy. For most patients, MVP carries a benign prognosis, and **periodic clinical follow-up examinations and reassurance** are all that is needed.

1. Endocarditis prophylaxis is not routinely indicated in patients with MVP.
2. Approximately 10% to 15% of patients, particularly those with redundant and thickened leaflets, eventually develop progressive MR. Chordal rupture is a contributing factor among these patients. **Management of MR** is outlined in **Section II.E.** Patients with evidence of primary MVP should avoid situations that might increase the stress on the chordae, such as sudden heavy lifting.
3. For patients with a history of **transient ischemic attacks, antiplatelet therapy with aspirin** (80 to 325 mg/d) is indicated. The ACC/AHA guidelines also recommend aspirin for poststroke patients with MVP who have no evidence of MR, atrial fibrillation, LA thrombus, or echocardiographic evidence of thickening (≥5 mm) or redundancy of the valve leaflets. However, long-term **anticoagulation therapy with warfarin** is recommended if any of these higher risk features are present, and in MVP patients with recurrent transient ischemic attacks while taking aspirin (international normalized ratio [INR]: 2.0 to 3.0). Aspirin is sufficient for patients with MVP and atrial fibrillation who are < 65 years, have no MR, and have no history of stroke, hypertension, or heart failure.
4. Patients who experience palpitations should be advised to abstain from caffeine, alcohol, and tobacco use. **β-Blockers** are useful in the management of premature atrial or ventricular contractions and often alleviate symptoms. **Ambulatory electrocardiographic monitoring** is recommended for persistent palpitations. Ventricular tachycardia is an indication for **electrophysiologic testing** to assess the risk of sudden death and the possible need for **implantation of a defibrillator device.**

V. MITRAL STENOSIS. Although declining in incidence in the United States, rheumatic disease remains the predominant cause of MS. Other etiologic factors are listed in Table 16.5. In general, once symptoms begin to develop, there follows a period of about 10 years before they become debilitating. Once significant limiting symptoms develop, the 10-year survival rate is < 15%.

A. Clinical presentation

1. Signs and symptoms

a. There is often a **long asymptomatic course**, consisting of a couple of decades.

b. When symptoms do develop, **dyspnea** is common. Predominant symptoms are exertional dyspnea initially, followed by paroxysmal nocturnal dyspnea and orthopnea, which reflect elevated pulmonary venous pressure.

c. Precipitating factors, such as exercise, emotional stress, pregnancy, infection, or atrial fibrillation with a rapid ventricular response, can produce or dramatically worsen symptoms by generating increased transvalvular gradients and LA pressure. **Atrial fibrillation with rapid ventricular response is a classic exacerbating factor** and may produce pulmonary edema, even in those with mild MS. The LA dilation is a predisposing factor for the development of atrial fibrillation.

d. Hemoptysis can occur and likely represents rupture of small bronchial veins from elevated LA pressure.

e. Hoarseness occurs when the dilated left atrium impinges on the recurrent laryngeal nerve (Ortner syndrome).

f. LA dilation and stasis, particularly in the context of atrial fibrillation (persistent or paroxysmal), may cause thrombus formation and embolic events. **Cerebrovascular events, coronary embolization, and renal emboli and infarction** are all possible sequelae. The malformed valve is predisposed to the development of **endocarditis**.

g. Fatigue is common because of reduced cardiac output.

h. With long-standing MS and elevated pulmonary pressure, symptoms of **RV failure** may develop.

i. Patients with elevated pulmonary pressures may have **angina-like chest pain**, as a reflection of increased RV oxygen demand.

TABLE 16.5 Causes of Mitral Stenosis

Rheumatic: most common cause
Congenital
Parachute mitral valve: single papillary muscle to which chordae to both leaflets attach; results in mitral stenosis or mitral regurgitation
Supravalvular mitral ring
Systemic diseases: can cause valvular fibrosis
Carcinoid
Systemic lupus erythematosus
Rheumatoid arthritis
Mucopolysaccharidosis
Healed endocarditis
Prior anorectic drug use
Severe mitral annular calcification

2. **Physical findings**
   a. **Inspection and palpation.** Patients may have a **malar facial flush**. The jugular venous pulse can demonstrate a **prominent** a **wave** if there is elevated pulmonary vascular resistance and the patient is still in sinus rhythm. **Jugular venous pressure is elevated with RV failure**. In advanced cases with low cardiac output, **peripheral cyanosis** occurs. The **carotid upstrokes are usually normal** but are of low amplitude if there is diminished cardiac output. The apex beat is not displaced and the impulse can have a tapping quality due to a palpable first heart sound. An apical diastolic **thrill** may be felt in the lateral decubitus position and has a quality that simulates a purring cat. If there is pulmonary hypertension, a **parasternal RV lift with a palpable P_2** is present.
   b. **Auscultation.** The main auscultatory findings are shown in Figure 16.5.
      (1) The **opening snap** is the most characteristic auscultatory hallmark of MS. However, as the mitral valve becomes more calcified and immobile, the opening snap may be lost (just as S_1 becomes softer).
      (2) The **murmur** of MS is typically a low-pitched rumbling mid-diastolic murmur, heard best with the bell of the stethoscope with the patient in the left lateral decubitus position. Presystolic accentuation can be present whether or not the patient is in sinus rhythm (exact mechanism is unknown). Auscultation after a **brief period of exercise may accentuate the murmur** of MS as the increased output and heart rate increase the transvalvular gradient. The length of the murmur correlates better with the severity of MS than the loudness. **The longer the murmur and the shorter the time interval from S_2** to the opening snap, the more severe the MS.
      (3) Concomitant **conditions that result in decreased flow across the valve**, such as CHF, pulmonary hypertension, and aortic stenosis, may **reduce the diastolic murmur**. The presence of a loud S_1 may be the only clue to the presence of MS in these cases, particularly if pulmonary hypertension exists.
      (4) Auscultation of the lungs may reveal fine inspiratory crackles. However, it is remarkable that some patients with severe MS have clear lung fields, possibly due to lymphatic hyperfunction clearing the transudated alveolar fluid that would be expected from the elevated LA pressure.

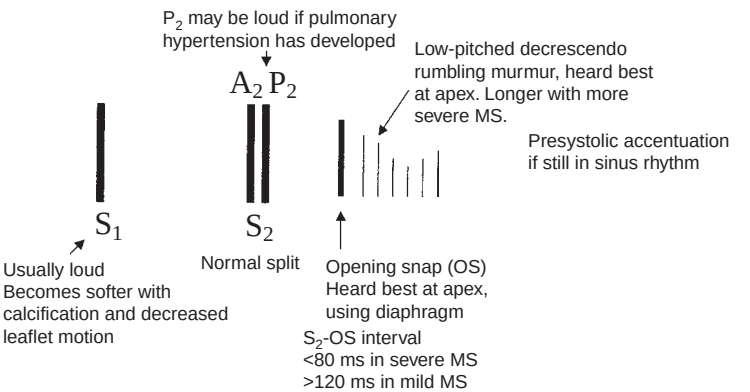

FIGURE 16.5 Auscultatory findings in mitral stenosis.

(5) Other **conditions that mimic** the clinical presentation of MS include LA myxoma and cor triatriatum. The tumor plop of myxoma may be mistaken for an opening snap, and tumor obstruction of the valve leads to a diastolic murmur. However, in this condition, the physical findings will vary with changes in position and from examination to examination. Other conditions in which a diastolic rumble may be present include atrial septal defect or VSD, the Austin-Flint murmur of aortic regurgitation (the murmur lessens with decreased afterload and is preceded by an S_3, and the S_1 is normal), and tricuspid stenosis (the murmur is heard at the left sternal border and typically increases with inspiration, known as Carvallo's sign).

B. Etiology (Table 16.5)

1. In **rheumatic MS**, up to 50% of patients are not aware of a history of rheumatic fever. Rheumatic fever is now rare in developed nations, although it is unclear whether this is due to improvements in living conditions or a change in the virulence or immunogenicity of *Streptococcus pyogenes*.
   a. In **acute** rheumatic fever, MR often predominates. Stenosis usually develops anywhere from 2 to 20 years later, and symptoms may not develop for many years thereafter. Although the incidence of rheumatic fever is roughly equal between men and women, rheumatic MS develops two to three times more frequently in women.
   b. Thickening of leaflets with **fibrous obliteration** is a characteristic finding. Commissural and chordal fusion and chordal shortening contribute to the development of stenosis. Calcium deposition occurs on leaflets, chordae, and annulus, further restricting valvular function. These changes collectively produce a funnel-shaped mitral valve with a fish-mouth orifice.
2. Nonrheumatic MS causes include congenital malformation, extensive annular calcification in the elderly, radiation heart disease, and restrictive mitral valve repair for MR.

C. Pathophysiology

1. The normal area of the mitral orifice is 4 to 6 cm^2. When the valve area is < 2 cm^2, a **pressure gradient between the left atrium and the left ventricle in diastole occurs**. As orifice area declines, both the transmitral pressure gradient and the LA pressure increase, but these are also affected by the flow through the valve. **Although the transmitral pressure is a useful indicator of MS severity, it is critically affected by the cardiac output at any moment**. The **cross-sectional area of the mitral valve orifice is, for the most part, independent of flow considerations and thus is a more robust measure of the severity of MS**.

   Typical findings indicative of the **severity of stenosis** as defined by the American Society of Echocardiography and endorsed by the recent ACC/AHA valve disease guidelines are as follows:
   a. **Severe** stenosis is associated with a **mean** transvalvular gradient **> 10 mm Hg**, PA pressures > 50 mm Hg, and a valve **area < 1.0 cm^2**.
   b. **Moderate** stenosis is associated with a **mean** transvalvular gradient of **5 to 10 mm Hg**, PA pressures of 30 to 50 mm Hg, and a valve area of **1.0 to 1.5 cm^2**.
   c. **Mild** stenosis is associated with a **mean** transvalvular gradient of **< 5 mm Hg**, PA pressures < 30 mm Hg, and a valve area **> 1.5 cm^2**.

   The severity of the stenosis needs to be assessed in terms of not only the valve area but also symptomatology and exercise capacity. Mixed MS and MR is often associated with greater symptomatic impairment than might be predicted from the severity of either lesion alone.
2. The **increased LA pressure is transmitted to the pulmonary vasculature**, resulting in symptoms of pulmonary congestion. The passive increase in pulmonary venous pressure may elevate pulmonary vascular resistance (reactive pulmonary hypertension). This condition is usually reversible if the stenosis is

relieved. However, in long-standing, severe MS, obliterative changes in pulmonary vasculature may occur. Severe pulmonary hypertension can in turn lead to right-heart failure.

3. Up to 30% of patients have a **depressed LVEF**. This appears to result from decreased preload (decreased inflow into the left ventricle) or a rheumatic myocarditis. The former will normalize after a corrective mitral valve procedure, the latter will not.
4. In severe MS, there may be sufficiently low cardiac output to cause **symptoms of poor perfusion**. Chronically depressed cardiac output causes a reflex increase in systemic vascular resistance and increased afterload. This may further diminish LV performance.

D. Laboratory examination and diagnostic testing

1. Echocardiography has several critical roles in the evaluation of MS (all endorsed by ACC/AHA recommendations): initial diagnosis, determination of severity, evaluation of suitability for percutaneous balloon mitral valvuloplasty, and identification of concomitant valve lesions.
   a. M-mode findings include dense echoes on the mitral valve and decreased excursion of the mitral valve. **Poor leaflet separation in diastole, anterior motion of the posterior leaflet, and decreased E–F slope on the anterior leaflet** are M-mode hallmarks of MS.
   b. Two-dimensional findings include restricted motion and diastolic doming of leaflets (hockey stick sign) (Fig. 16.6). The leaflets and chordae are thickened and are often calcified in older patients.
   c. Doppler echocardiography is **essential** in the assessment of stenosis severity.
      (1) A **transmitral peak velocity** > 1 m/s suggests MS. However, this is not specific because tachycardia, increased inotropy, MR, and VSD may cause increased flow in the absence of MS.

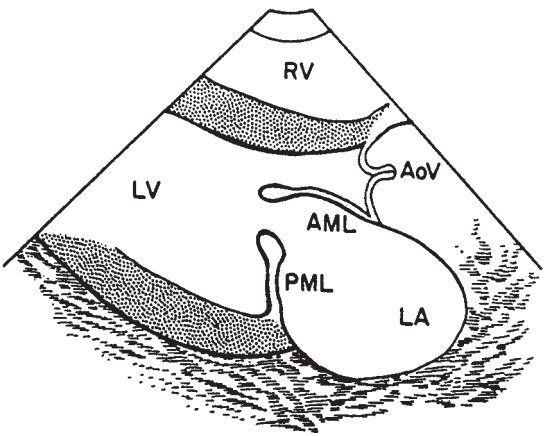

FIGURE 16.6 Two-dimensional echocardiographic scan in parallel long-axis view shows findings of mitral stenosis. Doming of leaflets is present. LV, left ventricle; RV, right ventricle; AML, anterior mitral leaflet; PML, posterior mitral leaflet; LA, left atrium; *AoV*, aortic valve. (Reproduced from Wilkins GT, Weyman AE, Abascal VM, et al. Percutaneous balloon dilatation of the mitral valve: an analysis of echocardiographic variables related to outcome and the mechanism of dilatation. *Br Heart J.* 1988;60:299–308, with permission from BMJ Publishing Group Ltd.)

(2) The **transvalvular mean gradient** (assessed by means of tracing mitral inflow) provides an estimate of the severity of stenosis. A mean gradient < 5 mm Hg is typical in mild stenosis. Moderate stenosis is associated with a mean gradient between 5 and 12 mm Hg. A gradient > 12 mm Hg suggests severe MS.

d. Echocardiography is used to estimate the **mitral valve area**.

(1) Direct planimetry of the orifice can be performed in the parasternal short-axis view.

(i) Optimal positioning is done by first obtaining a parasternal long-axis view and placing the mitral valve orifice in the center of the scan plane. The transducer is then rotated 90° to obtain the short-axis view. Measurements are obtained at the tips of the mitral leaflets.

(ii) Poor-quality 2D images and a thick, calcified subvalvular apparatus can make it difficult to obtain accurate measurements. Improper orientation of the scanning plane can produce oblique cuts across the valve and lead to overestimation of valve area. Scanning up and down until the typical fish-mouth appearance is seen helps in this regard. Dense fibrosis or calcification at the margins of the valve orifice can lead to underestimation of the valve area. Low-gain settings can cause dropout at the edges of the valve and overestimation of the valve area. High-gain settings can lead to underestimation. Planimetry is more difficult if commissurotomy has been performed, but remains the preferred method to assess the mitral valve area by means of echocardiography. With the advent of **3D imaging via transthoracic echocardiography**, more accurate orifice mapping for planimetry is now possible (see below).

(2) Pressure half-time method. Impedance to LA emptying prolongs the decline in transvalvular pressure gradient. This prolongs pressure half-time (time that it takes for pressure to fall to one-half the starting value, which equates with the time for the velocity to decrease to 70% of peak velocity). The mitral inflow E wave is used in the calculation.

(i) Empiric pressure half-time has been shown to correlate with valve area:

$$\text{Mitral valve area (in cm}^2\text{)} = 220/\text{pressure half-time}$$

(ii) If a software package to perform the calculations is not available, pressure half-time can be calculated by multiplying the deceleration time by 0.29. If atrial fibrillation is present, 5 to 10 consecutive beats are obtained and averaged.

(iii) It is important to have the Doppler beam parallel to the direction of blood flow.

(iv) The pressure half-time method **is inaccurate if there are rapid changes in LA hemodynamics**, such as immediately after balloon valvuloplasty.

(v) Obtaining a pressure half-time may be very difficult if sinus tachycardia is present (E–A fusion). Severe aortic insufficiency also fills the left ventricle in diastole, decreases pressure half-time, and leads to overestimation of the mitral valve area.

e. Stress echocardiography is useful in the evaluation of patients with symptoms when the **resting study is discrepant with symptoms or clinical findings** (ACC/AHA class I). Gradients can be assessed during (supine bicycle) or immediately after (treadmill) exercise. Measurement of tricuspid regurgitation velocity is used to estimate pulmonary pressures with stress.

f. **TEE** is indicated to exclude LA thrombus and assess MR prior to valvuloplasty, or if the TTE data are suboptimal (ACC/AHA class I), but is not indicated routinely if TTE data are adequate (ACC/AHA class III).

g. **Three-dimensional echocardiography (3DE)** can provide a 3D data set to determine the mitral valve area. This method can avoid error in measurement related to correct alignment of the cut-plane with the level of the mitral valve tips and speeds up the time required for optimal planimetry. Using real-time 3D transesophageal technology, visualization of the mitral valve en face from the left atrium or left ventricle is possible at the time of percutaneous balloon mitral valvuloplasty. The main advantage of preoperative transesophageal 3DE is that it replicates the surgical view of the mitral valve that will be seen upon opening the left atrium.

2. **Cardiac catheterization.** Hemodynamic measurements obtained in a cardiac catheterization laboratory are used to **assess the severity of stenosis**. Simultaneous measurement of LV end-diastolic pressure, LA pressure (either directly or more commonly with PCWP as a surrogate), cardiac output (Fick method or thermodilution), heart rate, and diastolic filling period (seconds per beat) is required. LV pressure and PCWP (or LA pressure) tracings are made simultaneously (Fig. 16.7). A mean transmitral gradient is derived from the preceding measurements (planimeter area between the left ventricle and PCWPs during diastole; this area is multiplied by the scale factor of the tracing in millimeters of mercury per centimeter to obtain the gradient). The PCWP tracing ideally should be realigned by 50 to 70 milliseconds to the left (with tracing paper) to account for the time delay in transmission of LA pressure to the pulmonary venous beds.

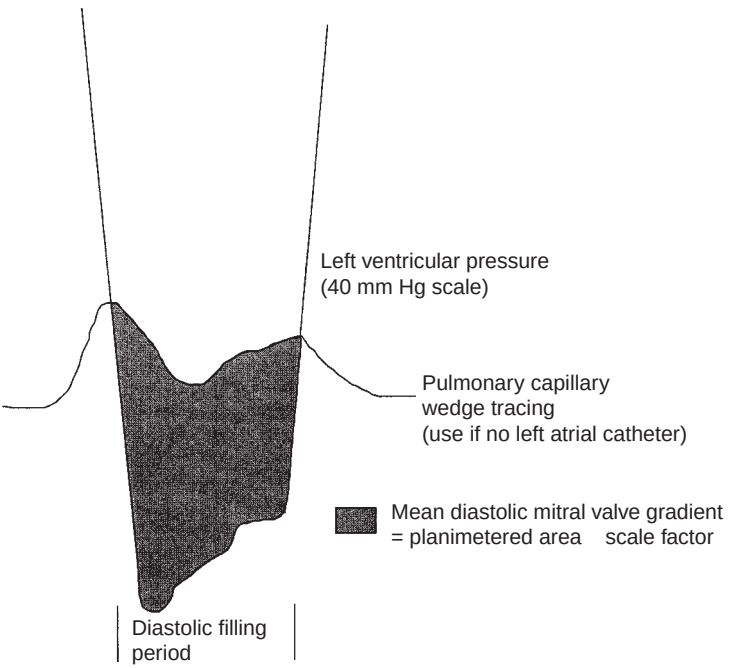

FIGURE 16.7 Simultaneous left ventricular and pulmonary capillary wedge pressure tracings used to measure mean gradient across mitral valve during diastole.

a. The **Gorlin formula:**

$$\text{Area} = \frac{\text{Cardiac output/diastolic filling period} \times \text{heart rate}}{37.7 \times \sqrt{(\text{mean transmitral pressure gradient})}}$$

Gorlin derived the empirical constant of 37.7, which is the Gorlin constant (44.3) multiplied by 0.85 (the correction factor for the mitral valve).

b. A **simplified version of the Gorlin formula** proposed by Hakki et al. has been validated and provides a reasonable approximation of the valve area:

$$\text{MVA} = \frac{\text{cardiac output}}{\sqrt{(\text{mean mitral gradient})}}$$

c. Pitfalls. PCWP cannot be used if the patient has pulmonary venous occlusive disease or cor triatriatum. The catheter must be properly wedged. In addition, **thermodilution cardiac output is less accurate** if there is severe tricuspid regurgitation or low cardiac output. **Immediately after valvuloplasty** MR or atrial septal defect, flow may lead to inaccurate estimations of mitral flow.

d. Cardiac catheterization is indicated in the evaluation of patients when echo-Doppler and clinical findings are discrepant (ACC/AHA class I) or when echo findings are internally discordant (class IIa) or if pulmonary hypertension is disproportionate to MS severity as assessed by echo (class IIa).

3. ECG. LA enlargement (P mitrale) is usually present when sinus rhythm persists. Signs of RV hypertrophy are seen with pulmonary hypertension. Atrial fibrillation is common and the fibrillatory waves are usually coarse.

4. Chest radiography. LA enlargement is apparent with a **double density** along the right heart border. A convexity can be apparent below the pulmonary artery, representing the LA appendage. Radiographic splaying of the carina with elevation of the left main bronchus and posterior displacement of the esophagus at barium swallow examination reflect LA enlargement. Kerley B lines may be present from increased pulmonary venous pressure. RV enlargement (decreased retrosternal air space on the lateral radiograph) may be present. Evidence of mitral valve calcification, or rarely LA calcification (McCallum's patch), may be present.

E. Therapy. The overall management approach to the individual with MS should integrate symptomatic status, degree of stenosis, and suitability of the valve for percutaneous balloon mitral valvuloplasty.

1. Medical therapy

a. Patients **without symptoms** who have mild MS (valve area > 1.5 cm^2 and mean gradient < 5 mm Hg) need no specific treatment and, **in accordance with current AHA guidelines, do not require endocarditis prophylaxis**. In patients with rheumatic valve disease, guidelines for the **prevention of rheumatic fever** should be applied. Annual reevaluation is recommended, but a yearly echocardiogram is not indicated unless there is a change in clinical status.

b. Patients with only **mild symptoms of exertional dyspnea** can be treated with **diuretics** and salt restriction to lower LA pressure. **β-Blockers** blunt the chronotropic response to exercise and may improve exercise capacity. **Arterial vasodilators should be avoided**.

c. Atrial fibrillation can clearly exacerbate symptoms, and **cardioversion or rate control measures** are important to maintain diastolic filling time. **Embolism** is a much feared complication of MS and occurs in up to 20% of patients; risk is increased with advancing age and atrial fibrillation.

(1) Digitalis and **β-blockers** are the preferred agents to achieve rate control.
(2) **Anticoagulation** with warfarin **is imperative** for patients with paroxysmal, persistent, or chronic **atrial fibrillation and MS** because they are at **high risk for thromboembolism** and this is also **indicated** in those with a history of **prior embolism or known LA thrombus** (ACC/AHA class I). Newer less emphatic recommendations (ACC/AHA class IIb) have been made for anticoagulation in MS patients with large atrial diameter (≥ 55 mm) or those with severe MS and enlarged LA size and evidence of spontaneous contrast on echocardiogram. The targeted INR is typically between 2.5 and 3.5.
(3) Antiarrhythmic drug therapy may be used in an attempt to restore sinus rhythm, but long-term efficacy may depend on correction of the MS.
(4) The role of percutaneous balloon mitral valvuloplasty in patients with new-onset atrial fibrillation and moderate to severe MS who are otherwise asymptomatic is controversial.

TABLE 16.6 ACC/AHA Indications for Percutaneous Mitral Balloon Valvotomy

Class I

1. PMV is effective for symptomatic patients (NYHA functional class II, III, or IV), with moderate or severe MS and valve morphology favorable for PMV in the absence of left atrial thrombus or moderate to severe MR
2. PMV is effective for asymptomatic patients with moderate or severe MS and valve morphology that is favorable for PMV, who have pulmonary hypertension (pulmonary artery systolic pressure > 50 mm Hg at rest or > 60 mm Hg with exercise) in the absence of left atrial thrombus or moderate to severe MR

Class IIa

PMV is reasonable for patients with moderate or severe MS who have a nonpliable calcified valve, are in NYHA functional class III–IV, and are either not candidates for surgery or at high risk for surgery

Class IIb

1. PMV may be considered for asymptomatic patients with moderate or severe MS and valve morphology favorable for PMV who have new-onset atrial fibrillation in the absence of left atrial thrombus or moderate to severe MR
2. PMV may be considered for symptomatic patients (NYHA functional class II, III, or IV) with MV area > 1.5 cm^2 if there is evidence of hemodynamically significant MS based on PA systolic pressure > 60 mm Hg, pulmonary artery wedge pressure of 25 mm Hg or more, or mean MV gradient > 15 mm Hg during exercise
3. PMV may be considered as an alternative to surgery for patients with moderate or severe MS who have a nonpliable calcified valve and are in NYHA class III–IV

Class III

1. PMV is not indicated for patients with mild MS
2. PMV should not be performed in patients with moderate to severe MR or left atrial thrombus

PMV, percutaneous mitral valvotomy; NYHA, New York Heart Association; MS, mitral stenosis; MR, mitral regurgitation; MV, mitral valve.

2. **Percutaneous or surgical therapy** (Table 16.6). **If more than mild symptoms** (New York Heart Association [NYHA] class II or greater) are present due to MS, the patient should be referred for surgical or percutaneous therapy. An asymptomatic patient, with moderate to severe MS and evidence of pulmonary hypertension at rest or with exercise, should also be referred for percutaneous therapy if the valve is suitable. Mortality increases substantially as symptoms progress. Results of natural history studies, conducted before valvotomy procedures were developed, indicate that young symptomatic patients have about 40% mortality at 10 years and almost 80% at 20 years. Elderly patients have 60% to 70% mortality at 10 years. Marked **pulmonary hypertension** (pulmonary arterial systolic pressure > 60 mm Hg) is an indication for mechanical treatment, even in the absence of symptoms in moderate to severe MS. Rarely, for **patients with asymptomatic MS** who do not have pulmonary hypertension, surgical or balloon intervention may be warranted. Instances where this is indicated include **women with severe MS contemplating to become pregnant**, those with severe MS who will need a major surgical procedure with massive fluid shifts, or those with repeated embolism despite anticoagulation. In the last instance, surgical intervention is usually indicated, and LA appendage ligation is performed simultaneously.
   a. **Percutaneous balloon mitral valvuloplasty is considered the treatment of choice for symptomatic patients with moderate to severe MS who have favorable valve morphology**. The technique involves placement of a balloon-tipped catheter into the left atrium through a transseptal puncture and then across the mitral valve. The hourglass-shaped balloon (Inoue balloon) is inflated and deflated to increasingly larger diameters until the desired result is obtained.
      (1) Typically, there is an increment in valve area of 1 cm^2, mainly as a result of splitting of the fused commissures. The mean valve area usually doubles with a 50% to 60% reduction in transmitral gradient.
      (2) This procedure is **generally contraindicated in patients with > 3+ MR** (the procedure normally increases MR by one grade) **or in whom there is an LA or appendage thrombus** (risk of procedural embolism). Severe tricuspid regurgitation (does not improve substantially) and severe pulmonary hypertension (if pulmonary artery pressures do not fall, then substantial risk of right-to-left shunt across procedural atrial septal defect) are relative contraindications to the procedure.
      (3) An **echocardiographic score** has been developed to help select patients who may be candidates for percutaneous valvuloplasty. There are four parts to the assessment (mobility, leaflet thickening, subvalvular thickening, and calcification) (Table 16.7). In general, extensive subvalvular disease results in a poorer outcome with valvuloplasty. Patients with extensive fluoroscopically visible mitral valve calcification also have a worse outcome after percutaneous therapy.
         (a) A total echocardiographic score (adding the four components) **higher than 11** is associated with a poorer outcome and a suboptimal increase in valve area, a higher incidence of heart failure and restenosis, and higher mortality. Patients with high scores **should not undergo valvuloplasty** unless surgical treatment is impossible.
         (b) Echocardiographic scores of **9 to 11** represent a **gray zone** in which some patients have good results with valvuloplasty. Others have suboptimal results.
         (c) Optimal results of balloon valvuloplasty are usually achieved when the echocardiographic score is **8 or less**.
      (4) TEE plays a critical role during valvuloplasty. The most immediate concern is to **rule out LA and appendage thrombi**. If thrombosis

TABLE 16.7 Echo Score Assessment for Percutaneous Valvuloplasty in the Management of Mitral Stenosis

Mobility (grade 0–4, 0 being normal)
1. Highly mobile with only leaflet tips restricted
2. Mild leaflet restriction; base portions have normal mobility
3. Valve moves forward in diastole, mainly from base
4. No or minimal diastolic movement of valve

Subvalvular thickening (grade 0–4, 0 being normal)
1. Minimal thickening below leaflets
2. Chordal thickening up to one-third of chordal length
3. Thickening extending to distal one-third of chords
4. Extensive thickening to papillary muscles

Thickening of leaflets (grade 0–4, 0 being normal)
1. Near normal (4–5 mm)
2. Marginal thickening (5–8 mm) with normal thickness of midleaflets
3. Thickening of entire leaflet (5–8 mm)
4. Extensive thickening of all leaflet tissues (> 8–10 mm)

Calcification (grade 0–4, 0 being normal)
1. Single area of echo brightness
2. Scattered areas of increased brightness along leaflet margins
3. Brightness extending to the midportion of leaflets
4. Extensive brightness throughout the leaflet tissue

Reproduced from Wilkins GT, Weyman AE, Abascal VM, et al. Percutaneous balloon dilatation of the mitral valve: an analysis of echocardiographic variables related to outcome and the mechanism of dilatation. *Br Heart J.* 1988;60:299–308, with permission from BMJ Publishing Group Ltd.

is present, anticoagulation for at least 1 month is undertaken with repeat TEE to confirm resolution before valvuloplasty. TEE can also help guide balloon positioning; after each inflation, the degree of MR and the gradient can be assessed. The degree of residual MS can be estimated with planimetry of the valve orifice before and after inflation. The pressure half-time method is unreliable until 24 to 48 hours after the procedure.

(5) Echocardiography is useful in the determination of immediate **postprocedural complications** (Table 16.8). Among these is MR with an incidence estimated at 3% to 8%, depending on the series. The echocardiographic score is less predictive of the severity of postprocedural MR.

TABLE 16.8 Complications of Balloon Valvuloplasty

Mitral regurgitation

Cardiac perforation: incidence as high as 2–4%

Embolization: incidence 2% in the National Heart, Lung, and Blood Institute registry

Residual atrial septal defect: most close within 6 mo; can persist long term among as many as 10% of patients; generally small and well tolerated

(6) The frequency of **restenosis of the valve** is variable, depending on the age of the patient and the immediate procedural increment in valve area. Data from the National Heart, Lung, and Blood Institute registry of all functional classes of patients show an 84% survival rate 4 years after treatment. Advanced age, high NYHA functional class, presence of atrial fibrillation, smaller initial mitral valve area, higher pulmonary arterial pressure, and substantial tricuspid regurgitation are **associated with poorer long-term results**. These variables identify a population with more serious illness that frequently necessitates intervention and should not preclude valvuloplasty. More postprocedural MR and lower postprocedural mitral valve area are associated with poorer long-term results.

b. Surgical treatment. Closed **commissurotomy** was the earliest surgical approach used. This was performed through a thoracotomy (without cardiopulmonary bypass) and atriotomy with a valve dilator. This procedure is rarely used in the United States since the development of the percutaneous approach and improvements in open-heart surgery. **Open mitral valvotomy** involves direct visualization of the mitral valve (with cardiopulmonary bypass), debridement of calcium, and splitting of fused commissures and chordae.

(1) Severe subvalvular disease or valvular calcification often leads to the choice of **surgical intervention over valvuloplasty**. Coexistent disease in other valves (e.g., aortic stenosis or aortic regurgitation) that necessitates treatment also favors surgical intervention.

(2) Mitral valve replacement. Valve replacement is often required, especially when there is **extensive fibrosis and calcification or concomitant MR**.

(3) Mitral valve repair is more difficult but can be performed in selected cases with commissurotomy when there is mixed MS/MR.

(4) For patients with long-standing **atrial fibrillation**, a combined maze procedure (either surgical or using an intraoperative ablation catheter) can be performed in conjunction with the valve operation. LA appendage ligation may also be added to reduce future cardioembolic risk.

c. Comparison of balloon valvuloplasty and open commissurotomy. Studies in ideal patients for balloon valvuloplasty and commissurotomy suggest equal improvement in valve area and symptoms immediately postprocedure and in medium-term follow-up.

d. Postprocedural follow-up care. Patients who have undergone balloon valvuloplasty or operations for MS should undergo baseline echocardiography, preferably > 72 hours after the procedure. In patients with a history of atrial fibrillation, warfarin should be restarted 2 to 3 days after the procedure. **Clinical follow-up examination** should be performed at least once a year and more often if symptoms develop. It has become common practice at many centers for patients to undergo **follow-up echocardiography on a once-a-year basis**, although no firm guidelines have been developed for this.

ACKNOWLEDGMENTS: *The authors wish to thank Carmel Halley, MD, and Maran Thamilarasan, MD, for their contributions to earlier editions of this chapter.*

Tricuspid Valve Disease, Pulmonary Valve Disease, and Drug-Induced Valve Disease

TRICUSPID VALVE DISEASE

I. INTRODUCTION. The **tricuspid valve (TV) apparatus** consists of three valve leaflets—septal, anterior, and posterior—along with the tricuspid annulus, the chordae tendineae, and the papillary muscles. Normally, the TV has an orifice area of 5 to 7 cm^2. The normal TV annulus is an elliptical and nonplanar structure, lying somewhat inferiorly and anterolaterally compared with the mitral valve (MV) annulus. The noncircularity and the nonplanarity of the TV have important mechanistic and therapeutic implications for correction of TV anomalies. Both tricuspid stenosis (TS) and tricuspid regurgitation (TR) can produce typical symptoms of right-sided congestive heart failure in their advanced stages. TV dysfunction can occur in both anatomically normal and abnormal valves.

II. TRICUSPID STENOSIS (TS). TS is rare as an isolated entity and is most commonly part of a multivalvular process. TS is usually organic in nature and is commonly encountered in conjunction with TR.

A. Etiology. Table 17.1 lists the causes of TS.

1. **Rheumatic heart disease (RHD)** by far is the most common cause of TS, accounting for > 90% of cases. Isolated TS is uncommon in these patients, and most patients have a combination of TS and TR. A large majority of patients with rheumatic TS have concurrent MV and aortic valve involvement. Clinically significant TV anomaly is present in only 5% of patients with RHD. Rheumatic TS is characterized by thickening and fibrosis of the valve leaflets, eventually culminating in marked leaflet contracture and commissural fusion.
2. **Carcinoid heart disease** is encountered in the setting of primary intestinal carcinoid tumors with secondary metastatic spread to the liver. Once metastatic to the liver, this neuroendocrine malignancy secretes numerous vasoactive substances (e.g., serotonin, histamine, and bradykinin), which directly affect the right-sided heart valves. Carcinoid valvular disease is characterized by thickened, retracted, shortened, and even fixed tricuspid leaflets, causing a mixed picture of regurgitation and stenosis. The pulmonic valve may also be involved. Unless there is a significant right-to-left shunt (via an atrial septal defect or patent foramen ovale), the left-sided heart valves are usually spared, owing to the clearance of vasoactive substances by the lungs.

B. Pathophysiology

1. TS produces a **diastolic pressure gradient** between the right atrium and the right ventricle, which is augmented when transvalvular flow increases. Therefore, the pressure gradient increases during inspiration or exercise and decreases during expiration. This typically occurs once the valve area falls below 1.5 cm^2.
2. A modest elevation of mean diastolic pressure gradient (i.e., ≥5 mm Hg) can raise right atrial pressure (RAP) (i.e., > 10 mm Hg) sufficiently to produce signs of **systemic venous congestion**, including hepatomegaly, ascites, and edema.
3. The right atrial *a wave* may be very prominent and may approach the level of the right ventricular systolic pressure (RVSP).
4. Resting cardiac output may be markedly reduced and may fail to augment with exercise, due to limited right ventricular preload.
5. Development of atrial fibrillation may result in higher RAPs due to the absence of organized atrial contraction and emptying.

C. Clinical presentation

1. **Signs and symptoms.** The presentation of TS varies depending on the **severity of stenosis**, the presence of **concomitant cardiac lesions**, and the **etiology of the valvular disease**.
   a. **Fatigue** is common and related to low and relatively fixed cardiac output.

TABLE 17.1 Causes of Tricuspid Stenosis

Disease entity
Congenital
Rheumatic
Infective endocarditis
Prosthetic valve failure
Carcinoid syndrome
Malignancy (e.g., myxoma and metastases)
Whipple's disease
Fabry's disease

b. **Right upper quadrant pain** can result from high systemic venous pressure and concomitant hepatomegaly, ascites, and abdominal distention.
c. Occasionally, patients will experience a **fluttering discomfort** in the neck, caused by the giant *a waves* transmitted to the jugular veins.
d. Severe TS may mask the typical symptoms of other coexisting valvular lesions, such as mitral stenosis (MS). In the case of MS, the flow limitation across the TV can minimize the pulmonary congestion, orthopnea, and paroxysmal nocturnal dyspnea usually associated with MS.

2. **Physical findings.** The diagnosis of TS is often missed without a high index of suspicion. Clues that should raise suspicion of TS include the presence of **elevated jugular venous pressure** and **accentuation of a diastolic murmur along the left sternal border with inspiration** (not present in MS).
a. Elevated central venous pressure may lead to marked hepatomegaly, ascites, and peripheral edema. In sinus rhythm, a giant *a* wave in the jugular venous pulse at the first heart sound (S_1) results from impaired right atrial diastolic filling during atrial systole.
b. **Diastolic murmur.** The murmur of TS is **low pitched**, **diastolic**, and best heard along the left lower sternal border in the third to fourth intercostal space or over the xiphoid process. If the rhythm is sinus, the murmur is prominent at end diastole (presystole). The low-pitched diastolic murmur may be obscured by the usually associated MS murmur. Accentuation of the murmur **intensity with inspiration** (Rivero-Carvallo sign) or other preload augmenting maneuvers (e.g., leg raising and squatting) may serve to differentiate the two murmurs or at least identify a component of TS in the setting of concurrent MS.
c. An **opening snap** (OS) may be heard at the left lower sternal border; however, this can be difficult to auscultate due to the commonly coexistent mitral OS.
d. Despite elevated neck veins and venous congestion, the patient may be comfortable lying flat due to the absence of pulmonary congestion. This apparent discrepancy between the severity of peripheral edema and the paucity of pulmonary congestion can help discriminate and identify TS from other valvular lesions.
e. Respiratory variation in splitting of the second heart sound (S_2) may be absent in patients with TS due to the relatively fixed diastolic filling of the right ventricle despite respiration.
f. In patients with the carcinoid syndrome, symptoms related to neurohormonal release, such as flushing and diarrhea, are typically more common than symptoms attributable to TS.

D. **Diagnostic testing.** The hemodynamic expression of TS is a pressure gradient across the TV in diastole. A mean diastolic pressure gradient of 2 mm Hg across the TV establishes the diagnosis of TS during catheterization. Nowadays, hemodynamic diagnosis is rarely required, as the diagnosis is usually apparent on Doppler echocardiography.

1. **Electrocardiogram (ECG).** TS is suggested by the presence of right atrial enlargement on the ECG (P-wave amplitude > 2.5 mV in lead II). Because of the common coexistence of MS, biatrial enlargement may be seen.
2. **Two-dimensional** (2D) **echocardiography**. The **echocardiogram is the most useful tool** in identifying TS. Typical findings **include reduction in the diameter of the TV orifice** and **thickening and diastolic doming of the tricuspid leaflets** (especially the anterior leaflet). Doppler interrogation of the TV will reveal increased transvalvular velocity; a mean pressure **gradient > 5 mm Hg using continuous-wave (CW) Doppler** is generally diagnostic of TS. Although it is possible to estimate the TV area by pressure half-time or planimetry, such measurements have limited utility in practice, as the severity of TS is more commonly described by the tricuspid diastolic pressure gradient. **Transesophageal echocardiogram (TEE)** is generally less useful than transthoracic echocardiogram (TTE) for assessing transvalvular gradients in TS, given that the TV is an anterior structure.

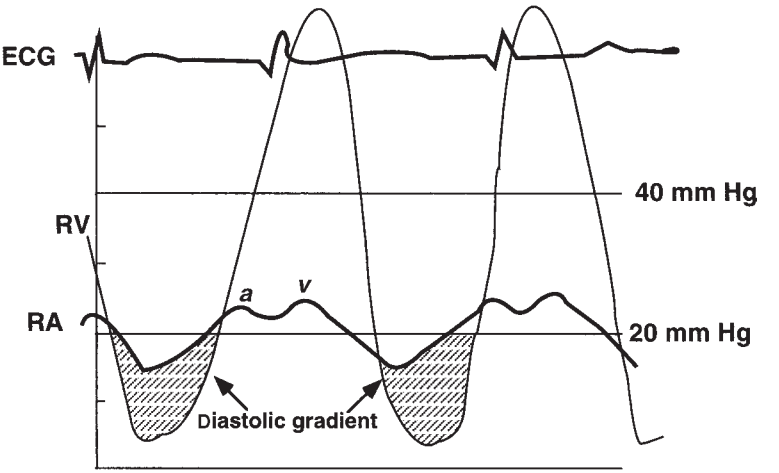

FIGURE 17.1 Tracings of simultaneous right atrial (RA) and right ventricular (RV) pressure waveforms in a patient with tricuspid stenosis.

3. **Three-dimensional (3D) echocardiography.** Given the complex 3D structure of the TV, 3D echocardiography (transthoracic or transesophageal) may prove to be a useful adjunct to standard 2D echocardiography. Using this modality, all TV leaflets can be simultaneously imaged, potentially allowing for more accurate calculation of TV area and precise visualization of leaflet motion.
4. Given the accuracy of modern echocardiographic techniques, cardiac catheterization can often be bypassed. **Right heart catheterization can be used to confirm the diagnosis** already suggested by Doppler echocardiography and can serve as a prelude to therapeutic balloon valvuloplasty. Cardiac output is typically low. The RAP is elevated and the *a wave* may be very tall, sometimes approaching the RVSP in magnitude. Simultaneous measurement of the right atrial and right ventricular pressures with dual catheters (or a dual-lumen catheter) enables the calculation of the diastolic pressure gradient (Fig. 17.1). The measured gradient is highly dependent on cardiac output and heart rate. Maneuvers such as lifting the legs or administration of atropine may accentuate the gradient.

E. Therapy

1. **Medical therapy** consists of intensive sodium restriction and diuretics.
2. **Defining coexisting valvular lesions** is critical to properly managing TS. For instance, in patients with combined TS and MS, the former should not be corrected alone, as this may produce pulmonary congestion. If other valvular surgery is planned, concomitant treatment of TS should be considered if the gradient exceeds 5 mm Hg or the TV orifice area is < 2.0 cm^2.
3. **Severe stenosis requires balloon valvuloplasty or TV replacement.** The indications for surgery or balloon valvuloplasty are usually determined by the severity of concomitant mitral or aortic valve disease. Limiting symptoms due to predominant TS are considered an indication for valvuloplasty or surgery. Balloon valvuloplasty appears to be successful from both a symptomatic and a hemodynamic standpoint, but can result in significant TR, potentially necessitating valve replacement.

4. **Bioprostheses are favored** when valve replacement is necessary at the tricuspid position, as **mechanical prostheses are more prone to thrombosis** at this location. Combined severe stenosis and regurgitation, as occurs with carcinoid disease, usually necessitates a surgical approach.

III. TRICUSPID REGURGITATION

A. Etiology and pathophysiology. Any disease process that causes derangement of the TV apparatus (annulus, leaflets, chordae, and papillary muscles) can lead to TR. The most common cause of TR is not intrinsic valvular disease but rather dilation of the right ventricle, causing secondary (functional) TR. Table 17.2 lists the causes of TR.

1. The most commonly encountered type is the **functional or secondary TR**. Functional TR refers to the TR secondary to the left or the right heart pathology in the face of **normal TV leaflet morphology**. Functional TR is a dynamic entity that is regulated by several factors, including annular dilation, annular shape, pulmonary hypertension, ventricular dysfunction, and leaflet tethering.
2. TR with an **anatomically abnormal valve (i.e., primary TR)** may be a manifestation of congenital heart disease (e.g., Ebstein's anomaly, atrioventricular canal defects, and ventricular septal defect [VSD]). In addition, a variety of conditions such as RHD, myxomatous degeneration, carcinoid heart disease, radiation, endomyocardial fibrosis, and the hypereosinophilic syndrome may cause scarring/thickening of the TV apparatus, resulting in poor leaflet coaptation and TR.

B. Clinical presentation

1. **Signs and symptoms.** The spectrum of symptoms of TR is wide and depends on its etiology and chronicity. **Isolated TR is usually well tolerated**. When TR and pulmonary hypertension coexist, cardiac output declines and patients

TABLE 17.2 Causes of Tricuspid Regurgitation

Primary causes

Rheumatic
Ebstein's anomaly
Carcinoid
Connective tissue disease (e.g., Marfan's syndrome)
Tricuspid valve prolapse
Trauma

Infective or marantic endocarditis
Papillary muscle dysfunction
Radiation injury
Toxic secondary to phen-phen or methysergide valvulopathy

Secondary (functional) causes

Right ventricular dilation (dilated annulus)
Pulmonary hypertension
Right ventricular dysfunction
—*Global: cardiomyopathy, myocarditis, infarction*
—*Segmental: ischemia, infarction, fibrosis, arrhythmogenic right ventricular dysplasia*

may manifest symptoms of right heart failure. Patients may present with painful **hepatic congestion and substantial peripheral edema. Fatigue** from reduced cardiac output is another common presentation. Patients may notice **pulsations in their neck** due to the prominent *cv wave* in the jugular venous pulse. TR often coexists with MV disease; in these patients, the symptoms associated with MV disease usually predominate.

2. **Physical findings**
   a. On general examination, patients with severe TR may have signs of weight loss, cachexia, and jaundice related to congestive hepatopathy and bowel edema.
   b. The neck veins will show loss of the usual *x* wave and a prominent systolic wave, usually referred to as a *cv* wave, followed by a rapid *y* descent. The characteristics of the large *cv* wave in the jugular venous pulse are dependent on TR severity. With significant TR, the prominent *cv* wave has maximal height at S_2, and the rapid *y* descent is most prominent on inspiration. A venous systolic thrill and murmur in the neck may be present in severe TR. The right ventricular impulse is often hyperdynamic.
   c. TR typically produces a **pansystolic murmur** at the third to fourth intercostal space along the left sternal border. The TR **murmur increases with inspiration (Carvallo sign)**.
   d. A TR murmur that develops **in the presence of pulmonary hypertension is usually high pitched** and pansystolic, whereas a TR **murmur of primary etiology** (from endocarditis or trauma) is **short** (limited to first half of systole) **and low pitched**.
   e. TR causes an increase in diastolic flow across the TV. This may be heard as an **early diastolic rumble** (short and low-pitched) along the left sternal border.
   f. With **severe, long-standing TR**, there is **ventricularization of the right atrium** (the pressure gradient across the TV is minimized), and the TR **may be barely audible or absent**.
   g. **Other findings.** A **right-sided third or fourth heart sound (S_3 or S_4) is often present along the left sternal border, which augments with inspiration. If pulmonary hypertension coexists, P_2** is accentuated. **Systolic pulsation** of the liver is often an associated physical finding, although this may be diminished once congestive cirrhosis develops.

C. **Diagnostic testing**
1. **Electrocardiography.** The findings are usually nonspecific. Incomplete right bundle branch block may be seen. Atrial fibrillation is commonly found in association with severe TR.
2. **Echocardiography.** The most common views used for the detection of TR are the parasternal right ventricular inflow, basal short axis, and the apical four-chamber views.
   a. **Physiologic TR.** A small degree of TR is observed in about 70% of patients with structurally normal hearts, and the prevalence increases with age. Physiologic TR is usually represented by a small jet that does not extend > 1 cm into the atrium.
   b. **Two-dimensional echocardiography**
      (1) Leaflet thickening may be seen in TR due to rheumatic or carcinoid disease. In functional TR, the leaflets usually appear normal. Tricuspid prolapse often occurs in patients with MV prolapse and may cause significant TR. In Ebstein's anomaly, the septal leaflet of the TV is displaced apically. Vegetations are evident with endocarditis, and a flail valve leaflet may be seen with iatrogenic damage (e.g., after endomyocardial biopsy) or following papillary muscle rupture with right ventricular infarction.
      (2) With moderate to severe TR, a **right ventricular volume overload pattern** is seen, characterized by right ventricular enlargement, ventricular septal flattening or shift to the left in diastole, and paradoxical motion in

systole. There is often associated dilation of the right atrium and inferior vena cava (IVC).

c. Doppler analysis. Assessment of TR involves incorporation of all of the Doppler information obtainable: size of the color jet, presence or absence of a proximal convergence zone (on the right atrial side of the valve), velocity profile, and eccentricity of the TR jet. Eccentric, wall-hugging jets should be typically upgraded by one grade, as is done for mitral regurgitation, because these are generally not visualized fully by echocardiography.

(1) TR direction and severity are assessed with color-flow Doppler. The severity of TR is estimated in several ways, including

(a) Jet area—This measure is highly dependent on echocardiographic settings, particularly the pulse repetition frequency, and the direction and eccentricity of the jet.

(b) Vena contracta width—The narrowest portion of the jet just downstream from the valve orifice gives a rough estimate of the effective orifice area. A jet width of > 0.7 cm suggests severe TR.

(c) Proximal flow convergence (see Chapter 16).

(d) CW Doppler—The signal intensity and contour of the TR jet on CW Doppler can help define TR severity. Severe TR produces a dense spectral recording along with a triangular, early peaking velocity.

(e) Hepatic vein flow—Systolic flow reversal in the IVC or hepatic veins is consistent with severe TR.

(2) The RVSP is estimated using the modified Bernoulli equation after measuring the peak TR jet velocity by CW Doppler. In the absence of pulmonic stenosis, the pulmonary artery systolic pressure (PASP) can then be estimated as PASP = RVSP + RAP.

3. Cardiac catheterization. In the presence of moderate to severe TR, right heart catheterization will show a dominant *v* wave in the RAP curve (Fig. 17.2), an RAP curve resembling that of the right ventricle, increased right ventricular end-diastolic pressure, and low cardiac output by thermodilution and Fick techniques. **Angiocardiography** involves injecting contrast into the right

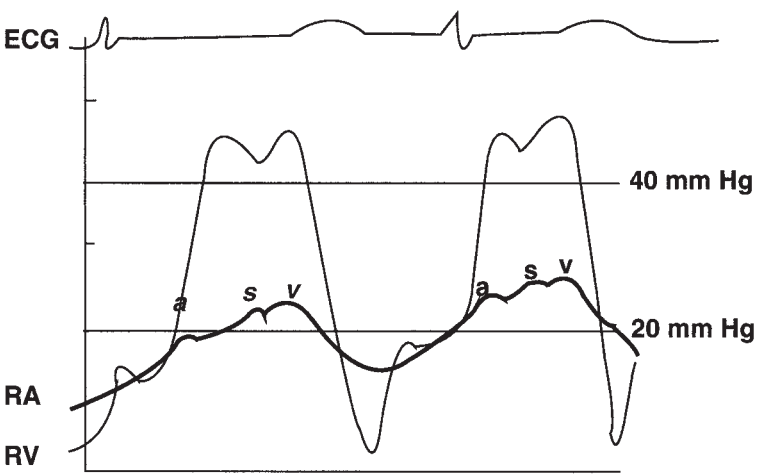

FIGURE 17.2 Tracings of simultaneous right atrial (RA) and right ventricular (RV) pressure waveforms in a patient with tricuspid regurgitation.

ventricle while viewing the right anterior oblique projection. This method allows for visualization and semiquantification of the TR jet but is rarely performed, as echocardiographic techniques are more reliable.

D. Therapy

1. In the absence of pulmonary hypertension, mild to moderate degrees of TR can be well tolerated for many years, and surgery is not recommended (American College of Cardiology/American Heart Association [ACC/AHA] class III). If right ventricular failure develops, **medical therapy** should be targeted at diuretic therapy and afterload reduction, as in other heart failure states.
2. **Surgical therapy.** When there is an **organic cause** of moderate to severe TR, **surgical repair or replacement** may be necessary depending on the symptoms and the degree of leaflet destruction/damage. Currently, there is a lack of a clear consensus regarding indications for surgical repair of mild to moderate functional TR. ACC/AHA recommends surgical repair of severe TR in the setting of multivalvular disease (class I). Several studies have demonstrated a significant improvement in the functional status among individuals undergoing concomitant TV repair with MV or AV surgery in comparison to those undergoing left heart valvular surgery alone. In addition to multivalvular disease, tricuspid annuloplasty is recommended in patients undergoing MV surgery when there is pulmonary hypertension or significant TV annular dilation (class I). Most commonly, surgery for TR is considered in combination with left heart valvular surgery. In patients with MS and TR, a decision to repair the TV should be based on the severity of the TR, as well as the duration and severity of pulmonary hypertension (i.e., TR in the setting of long-standing pulmonary hypertension and MS is unlikely to improve with MV surgery alone). Usually tricuspid repair or annuloplasty is favored over prosthetic implantation where this is feasible. The other situations where TV repair may be considered include severe TR with deteriorating exercise capacity (ACC/AHA class I), severe TR with atrial fibrillation (ACC/AHA class IIa), and progressive enlargement of an already dilated right ventricle (ACC/AHA class IIb).

PULMONARY VALVE DISEASE

I. INTRODUCTION. The pulmonary valve is a trileaflet valve that separates the right ventricle from the pulmonary vasculature. Dysfunction of the valve can have adverse effects on the right ventricle by producing pressure and/or volume overload. A small degree of pulmonic regurgitation (PR) may be a common finding in healthy adults. Acquired pulmonary valve disease is rare in comparison with other valvular disorders.

II. VALVULAR PULMONARY STENOSIS (PS)

A. Etiology

1. **Congenital** PS is the most common pulmonary valve problem, occurring in approximately 10% to 12% of all adult patients with congenital heart disease. Valvular PS is typically an isolated abnormality, but it may occur in conjunction with VSD.
2. **RHD** can affect the pulmonary valve, although this is uncommon and usually occurs in the setting of multivalvular involvement. This can result in thickening and fusion of the valve leaflets, resulting in PS.
3. As with the TV, **carcinoid heart disease** (see Section **II.A.2**) can affect the pulmonary valve, causing formation of typical "carcinoid plaques." The plaques may result in constriction of the pulmonic valve ring, retraction and fusion of the cusps, and usually a combination of PS and PR.
4. Rarely, pseudopulmonary valve stenosis can occur as a result of **right ventricular outflow obstruction** from cardiac tumors or from an aneurysm of the sinus of Valsalva.
5. Although most cases of isolated PS are valvular, **obstruction may occur below the valve in the right ventricular outflow tract or above the valve at the junction with the main pulmonary artery**. Congenital PS is most frequently

caused by a dysplastic valve and less frequently a bicuspid valve. Right ventricular hypertrophy from the pressure overload of the PS on the right ventricle may cause concomitant right ventricular outflow tract obstruction, which usually reverses following successful dilation of the valvular stenosis.

B. Clinical presentation

1. **Signs and symptoms.** Patients with isolated PS present most commonly in the fourth or fifth decade of life with signs and symptoms of right heart failure and dyspnea on exertion. Of note, many patients with moderate PS remain asymptomatic. When the stenosis is severe, patients may occasionally have retrosternal chest pain or syncope with exertion. If the foramen ovale is patent, right-to-left shunting may occur, producing cyanosis and clubbing.
2. **Physical findings**
   a. PS causes a systolic crescendo–decrescendo murmur, heard best in the third and fourth intercostal spaces, with delayed peaking of the murmur in severe cases. The murmur typically increases with inspiration. A thrill may be felt in the suprasternal notch and at the left upper sternal border. S_2 is often split widely, and the degree of the splitting increases with worsening stenosis due to delay in P_2. The intensity of P_2 may be increased in mild stenosis but is usually diminished with severe stenosis. An ejection click can sometimes be heard along the left sternal border, and it may vary with respiration. As severity of PS increases, the click will move closer to S_1.
   b. The right ventricular impulse may be palpated at the left sternal border and be hyperdynamic.
   c. The jugular venous pressure can be normal. However, in patients with reduced right ventricular compliance, a prominent *a* wave may be seen in the venous pulse. A right-sided fourth heart sound (RV S_4) may be heard at the left lower sternal border.
   d. In advanced cases, evidence of right-sided heart failure may be present, including hepatic congestion and peripheral edema.

C. Diagnostic testing

1. **Electrocardiogram.** In patients with moderate to severe PS, the ECG may show right-axis deviation and right ventricular hypertrophy.
2. Chest radiography may reveal **poststenotic dilation** of the main pulmonary artery and diminished pulmonary vascular markings.
3. **Echocardiography** is useful in diagnosing pulmonary valve stenosis and for quantifying the severity of the obstruction. The best images of the pulmonary valve are obtained from the short-axis view at the level of the base from the parasternal and subcostal windows. Transesophageal echocardiography is useful when the TTE images are suboptimal.
   a. **Leaflets.** In adults, the leaflets can appear thickened and calcified with restricted motion. In children with congenital PS, the leaflets are noncalcified with doming of the valve.
   b. **Right ventricle.** The right ventricle may be normal, especially in children. Right ventricular dilation and hypertrophy may be seen in adults, depending on the severity and the duration of this disease.
4. **Doppler echocardiography** is the preferred method for grading the severity of PS. This method of quantifying the degree of stenosis is well correlated with the direct measurement obtained during cardiac catheterization. The peak gradient is measured across the pulmonary valve by using CW Doppler with the modified Bernoulli equation. The following levels of severity have been defined in the 2006 ACC/AHA guidelines on the management of valvular heart disease:
   (a) Severe stenosis: a peak jet velocity of > 4 m/s (peak gradient > 60 mm Hg).
   (b) Moderate stenosis: peak jet velocity of 3 to 4 m/s (peak gradient 36 to 60 mm Hg).
   (c) Mild stenosis: peak jet velocity of < 3 m/s (peak gradient < 36 mm Hg).

D. Therapy

1. Mild to moderate PS generally has a good prognosis, and intervention is rarely necessary. Survival is excellent among patients with mild PS, with 94% patients alive as long as 20 years after diagnosis.
2. Patients with severe PS usually warrant a therapeutic intervention for relief of stenosis. The treatment of choice is **balloon valvuloplasty**, usually leading to a 75% decrement in the transvalvular gradient after a successful procedure. The procedure is usually successful if the valve is mobile and pliable. Prognosis and morbidity subsequent to the procedure are largely based on right ventricular function at the time of the procedure. The hypertrophic subpulmonary stenosis that may accompany valvular stenosis usually regresses after successful valvuloplasty. Valve replacement may be necessary if the valve is severely calcified or if there is severe concomitant TR.
3. The **ACC/AHA guidelines for intervention** in congenital PS are as follows:
   Class I: Balloon valvuloplasty is indicated in symptomatic patients with > 30 mm Hg gradient (peak–peak) across the pulmonary valve at cardiac catheterization and in asymptomatic patients when this gradient is > 40 mm Hg.
   Class II: Balloon valvuloplasty may be reasonable if the gradient across the pulmonary valve is 30 to 39 mm Hg by cardiac catheterization in an asymptomatic adolescent or young adult.
   Class III: Balloon valvuloplasty is not indicated in asymptomatic patients whose pulmonary valve gradient is < 30 mm Hg at catheterization.
4. PS secondary to **carcinoid syndrome** has a very poor prognosis (with a median survival of 1.6 years), and the valve often does not respond to balloon valvuloplasty. **Valve replacement** is often necessary.

III. VALVULAR PULMONARY REGURGITATION (PR)

A. Etiology. PR is most commonly produced secondary to dilation of the valve ring due to pulmonary hypertension or dilation of the pulmonary artery.

1. **PR may occur secondary to rare congenital causes**, such as an absent, malformed, or fenestrated leaflet. In the setting of repaired tetralogy of Fallot, PR is a common and difficult problem, often contributing to progressive right ventricular dilation and dysfunction.
2. Acquired causes of pathologic PR are much more common. **The most common acquired cause is pulmonary artery hypertension**, followed by infective endocarditis. Both carcinoid syndrome and RHD may cause PR but they are more likely to cause PS. Marfan's syndrome may cause PR secondary to dilation of the pulmonary artery. Iatrogenic PR may be caused by placement of a pulmonary artery catheter.

B. Clinical presentation

1. **Signs and symptoms.** Like TR, PR causes volume overload of the right ventricle. However, in the absence of significant pulmonary hypertension, it may be tolerated well for many years. Once symptomatic, the patients with PR present with the signs and symptoms of **right heart failure and exertional dyspnea**. In the setting of PR caused by infective endocarditis, patients may present with fever and hypoxia due to septic pulmonary emboli.
2. **Physical findings**
   a. The murmur of PR is a relatively brief **low-pitched, diamond-shaped, diastolic murmur**, heard best in the third and fourth left intercostal spaces with a widening of S_2. The murmur increases with inspiration, and **P_2 is accentuated** in the presence of pulmonary artery hypertension.
   b. The **Graham Steell murmur** is a high-pitched, blowing decrescendo diastolic murmur starting immediately after P_2, which is accentuated by inspiration.

This characteristic murmur occurs when PASP exceeds 70 mm Hg in the presence of PR.

c. A right ventricular S_3 and S_4 may be audible in the fourth intercostal space and will be augmented by inspiration. Depending on the severity and duration of the regurgitant valve, signs and symptoms of right heart failure may also be present on examination.

C. Diagnostic testing

The pulmonary valve is best evaluated with **echocardiography**, using the left ventricle short-axis view from the parasternal and subcostal windows. Minor degrees of PR are seen in 40% to 78% of normal individuals. Pathologic PR is relatively infrequent and should be diagnosed in the context of other structural abnormalities.

1. **Anatomic assessment.** The right ventricular outflow tract and pulmonary valve should be interrogated for abnormalities such as leaflet hypoplasia, increased cusp number, and abnormal valve motion (i.e., doming).
2. **Right ventricle.** The size and function of the right ventricle can provide an indicator of the severity of PR (i.e., long-standing severe PR should be associated with right ventricular dilation and/or hypertrophy).
3. Color-flow Doppler will reveal a regurgitant jet toward the right ventricle during diastole. Jet length is determined primarily by the pressure difference between the pulmonary artery and right ventricle and, therefore, is an unreliable indicator of PR severity. The **vena contracta** is probably a better measure of PR severity.
4. CW Doppler will show a dense spectral signal and rapid equilibration of diastolic pressures in severe PR. Maintenance of the regurgitant velocity during diastole suggests that **pulmonary hypertension** is the cause of valve incompetence. Furthermore, increasing pulmonary artery pressures correlate with decreasing acceleration times of pulmonary artery flow. Pulmonary artery pressures can be obtained using Doppler flow measurements and the following equation. Pulmonary artery diastolic pressure (PADP) is only obtainable in the setting of PR:

$$\text{PADP} = 4(V_{\text{PR-E}})^2 + \text{RA}_{\text{pressure}}$$

where $V_{\text{PR-E}}$ is the end-diastolic PR velocity.

D. Therapy

1. **Primary pulmonary valve regurgitation.** The prognosis is very good; rarely is correction of the defect necessary, except in cases of intractable right heart failure.
2. **Secondary pulmonary valve regurgitation.** The prognosis due to endocarditis, carcinoid, or pulmonary artery hypertension is dependent upon the prognosis and treatment of the primary disease. Treatment of the primary condition (e.g., repairing MV in the setting of pulmonary hypertension) often ameliorates the PR. Besides this, vasodilating therapies for pulmonary hypertension can reduce secondary PR. When a treatment is absolutely necessary, **the preferred approach is valve replacement with a bioprosthesis or a pulmonary allograft**. Percutaneous deployment of a prosthetic valve has been successfully accomplished in this setting and is under active investigation currently. Annulus repair is ideal in patients with coexisting left-sided valvular lesions.

DRUG-INDUCED VALVE DISEASE

I. INTRODUCTION. Most common forms of valve disease are inherited or acquired in response to a specific disease process. Over the last three decades, however, it has become clear that several pharmacologic agents may produce a cardiac valvulopathy, which mimics other etiologies of valvular disease.

II. DRUGS KNOWN TO CAUSE VALVE DISEASE

A. Ergot alkaloid derivatives (ergotamine and methysergide) used for migraine prophylaxis have been reported to cause valvulopathy since the early 1990s.

B. In 1997, Connolly et al. reported that both **fenfluramine** and **dexfenfluramine**, the constituents of popular diet pills, were associated with valvular heart disease with a typical histologic appearance (described in subsequent text). This led to the withdrawal of a number of common diet drugs from the market. At their peak usage, about 14 million prescriptions had been written for these medications.

C. More recently, valvular heart disease was reported in 24% to 28% of patients undergoing treatment of Parkinson's disease with **ergot-derived dopamine agonists (pergolide and cabergoline)**.

D. There is an increased risk of valvulopathy in individuals with heavy and frequent use of the recreational drug, **3,4-methylenedioxymethamphetamine (MDMA)**. This drug, popularly known as *ecstasy*, has become one of the most frequently used party drugs in Western Europe and the United States over the last two decades.

E. Thus far, there has been no convincing evidence of valvular heart disease with the use of other serotonergic drugs (e.g., selective serotonin reuptake inhibitors).

III. PATHOLOGY AND PATHOGENESIS

A. Valves that are surgically removed from patients using these drugs are described as having a white, glistening appearance, with histologic evidence of a plaquelike process extending along the leaflet and encasing the chordae tendineae. These findings are **very similar to the findings seen in patients with valvular disease due to carcinoid tumors**, which also secrete vasoactive amines.

B. Subsequent research has indicated that valvulopathic drugs may act via their ability to stimulate the serotonergic receptors, particularly the 5-hydroxytryptamine $(5\text{-HT})_{2B}$ serotonin receptor. This receptor is plentiful in normal heart valves and appears to be essential for normal cardiac development. Stimulation of the 5-HT_{2B} receptor appears to cause mitogenic stimulation of normally quiescent valve cells, causing an "overgrowth" valvulopathy.

IV. PREVALENCE. Estimates of the prevalence of drug-induced valvular disease have varied widely. Initial studies based on case series suggested a prevalence of valve disease as high as 20% to 30% in the setting of fenfluramine exposure, but larger population-based studies suggest a much lower prevalence of around 10% to 12% (vs. 5% to 6% in control group). **Factors that appear to be associated with a greater prevalence of valvular disease include duration of treatment, use of combination agents, and shorter time from cessation of drug treatment to evaluation**. The prevalence of disease is highest in those who have been on a valvulopathic medication for **> 6 months**.

V. CLINICAL PRESENTATION. Most commonly, patients seek advice based on a history of taking ergot-derived medications or diet drugs, given the media attention associated with this condition and the legal action that has been mounted against the drug manufacturers. Patients may also present with symptoms of valve disease, such as dyspnea and fatigue. **The predominant findings on examination in patients with significant valve disease involve regurgitation of the AV, the MV, or the TV**. Although the right-sided valves are usually involved, the ergot derivatives may also affect the left-sided valves and cause valvular regurgitation. Aortic regurgitation is reported with increased frequency in those with anorexient abuse than regurgitation at other valve locations.

VI. EVALUATION. Patients suspected of having valve lesions on examination or those in whom a cardiac examination is somewhat limited by obesity and who have been exposed to diet drugs should undergo echocardiography. The echocardiographic features simulate both rheumatic disease and carcinoid disease with **leaflet thickening and doming of the MV and thickening of the AV or the TV leaflets**. Despite the apparent restriction of motion of the leaflets, clinically significant **stenosis is rare**. Regurgitation, when present, may be of any grade or severity, although it is generally

mild. However, severe regurgitation requiring surgery has been reported with diet drug–induced valve disease.

VII. TREATMENT. Once drug-induced valve disease is suspected, the offending drug should be discontinued immediately. In the case of anorexient-induced valve lesions, **mild improvement in the severity of the valvular regurgitation has been reported on medium-term follow-up after drug discontinuation**. Progression in the severity of valvular disease following drug discontinuation is relatively uncommon. Indications for the surgical intervention in drug-induced valvulopathy are similar to those of other disease processes. However, watchful waiting is a prudent approach in these patients, given the potential for some reversibility of the valve lesions upon drug discontinuation. Endocarditis prophylaxis is not indicated in those with evidence of drug-induced valve disease, per the most recent ACC/AHA guidelines.

VIII. FOLLOW-UP. Patients with valve disease should be evaluated both clinically and with echocardiography initially every 6 months. In those with mild stable lesions, yearly evaluation is appropriate.

ACKNOWLEDGMENTS: *The authors thank Drs. Amy P. Scally, Deepu Nair, and Marc Penn for their contributions to earlier editions of this chapter.*

CHAPTER 18

João L. Cavalcante

Prosthetic Heart Valves

Prosthetic valve replacement still represents the treatment of choice for severe native valve dysfunction, especially for rheumatic disease, which remains the most frequent cause of replacement worldwide. This chapter discusses the types of prosthetic valves, indications, and prosthetic valve choices and provides a brief overview of the recent developments in transcatheter aortic valve replacement (TAVR).

I. INDICATIONS FOR IMPLANTATION

A. Types of prosthetic valves. Prosthetic valves are classified into two major categories: mechanical and bioprosthetic. Each model differs in its durability, thrombogenicity, and hemodynamic performance. Various mechanical and bioprosthetic valves are shown in Figure 18.1.

1. Bioprosthetic valves. These resemble native valves but have a slightly less optimal hemodynamic performance, owing to the reduction in flow profile by interposed stents and the sewing ring.

a. Heterografts

(1) Carpentier-Edwards valves are made of either bovine pericardium (aortic position), which have greater durability, or porcine leaflets mounted on a cloth-covered annular ring and supported by steel alloy flexible stents at each of the commissures.

(2) The Hancock II stented porcine valve (Medtronic) has been considered as the porcine bioprosthetic valve with the best hemodynamics and longevity available. The supraannular prosthetic sewing ring improves hemodynamic performance; and modern preservation techniques using low-pressure fixation and treatment with sodium dodecyl sulfate increase longevity by delaying calcification. The durability of bioprosthetic bovine pericardial versus porcine valves is controversial, although many consider that the pericardial valves may have some durability advantage in younger patients.

(3) For the **stentless porcine bioprostheses** (Medtronic Freestyle or St. Jude Medical), there are three different methods for implantation, with the subcoronary valve replacement being the most common. Although the stentless valves offer a better hemodynamic profile owing to the larger effective orifice area (EOA), convincing advantages in terms of mortality, left ventricular (LV) mass regression, and durability (when compared with pericardial and not porcine valves) have yet to be demonstrated.

(4) Since the first-in-man **TAVR** done by Cribier in 2002, more than 40,000 patients have undergone TAVR worldwide (see Chapter 66). The technology has evolved tremendously and is now transforming the management of patients with critical aortic stenosis who are high-risk surgical candidates. The ground-breaking Placement of AoRtic TraNscathetER Valves (PARTNER) trial changed the paradigm. It randomly assigned

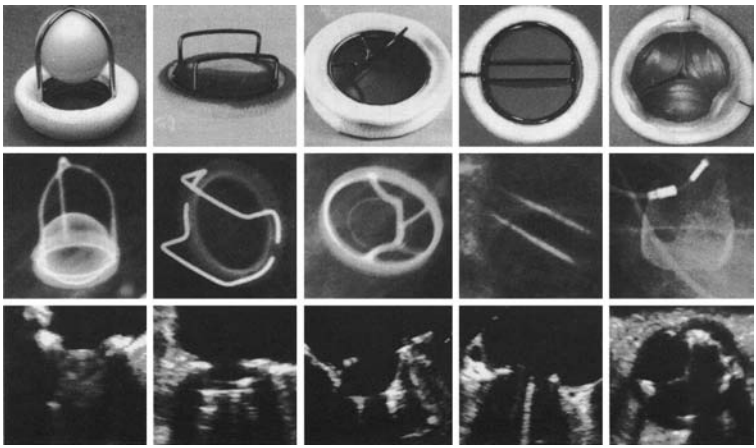

FIGURE 18.1 Photographic and radiographic appearance of different prosthetic heart valves. From left to right: Starr-Edwards caged ball, Kay-Suzuki caged disk, Björk-Shiley single-tilting disk, St. Jude's bileaflet tilting disk mechanical valves, and Carpentier-Edwards xenograft. (From Garcia M. Principles of imaging. In: Topol EJ, ed. *Comprehensive Cardiovascular Medicine*. Philadelphia, PA: Lippincott-Raven Publishers; 1998:610.)

patients ($n = 358$) with severe aortic stenosis, whom surgeons considered not to be suitable candidates for surgery, to standard therapy (including balloon aortic valvuloplasty) or transfemoral transcatheter implantation of a balloon-expandable bovine pericardial valve. The primary end point was the rate of death from any cause.

The results showed that this approach was associated with a significant reduced 1-year mortality for patients with severe aortic stenosis who are not surgical candidates due to advanced comorbidities (50.7% for medical treatment vs. 30.7% in the TAVR group; hazard ratio with TAVR, 0.55; 95% confidence interval [CI], 0.40 to 0.74; $p < 0.001$). The valve tested was Edwards SAPIEN heart valve system (Edwards Lifesciences) that consisted of a trileaflet bovine pericardial valve and a balloon-expandable, stainless steel support frame (Fig. 18.2).

The second largest experience, mostly European, is with the self-expanding Medtronic CoreValve ReValving system. It uses a porcine pericardial valve in a larger and self-expandable nitinol frame, which covers both the left ventricular outflow tract (LVOT) and the aortic root. It has also demonstrated similar trends in outcome, although with slightly higher incidence (up to 25%) of atrioventricular block requiring pacemaker implantation.

The long-term durability of these valves has been addressed only in small studies. Theoretically, and according to the manufacturer's wear test, both transcatheter valve systems are designed to last ≥10 years. All published studies suggest good durability and preserved hemodynamic function, with EOAs over 1.5 cm^2 at 3 years. Paravalvular leak has been a concern with these valves, but this is generally mild and does not usually progress significantly at least over medium-term follow-up.

B

FIGURE 18.2 Transcatheter aortic valve prosthesis currently available for clinical use (*). **A:** Balloon-expandable Edwards SAPIEN XT valve (Edwards Lifescience, Irvine, CA). **B:** Self-expanding CoreValve ReValving System (Medtronic, Minneapolis, MN). (*) The CoreValve system is currently not approved yet by FDA for clinical use in the USA.

b. Aortic homografts are cryopreserved cadaveric human aortic valves. These are typically implanted stentless, with a short segment of the donor's aortic root for support. The coronary arteries require reimplantation. The hemodynamic profile of the homograft is similar to that of the native valve. Availability of homografts is a limiting factor.

c. Autograft. An autograft is a procedure in which the patient's own valve is moved from its normal anatomical position to another site. Typically, this is done with the pulmonary valve in patients with significant aortic valve disease. A pulmonary homograft is placed at the native pulmonary position. This operation is called the Ross procedure, after the surgeon who popularized it. This procedure has the advantage of putting a native valve at the hemodynamically most important position. It has been advocated for younger patients, and some reports suggest that the autograft may grow with the patient, which is advantageous in the adolescent age group. However,

the initial enthusiasm with this procedure has been tempered by suboptimal outcomes in many adult patients, particularly with regard to the pulmonary homograft. Additionally, progressive root enlargement may ensue in patients with bicuspid valve and ascending aortic dilatation, leading to autograft failure. The decision to proceed to autograft implantation in adults should be considered very carefully and in consultation with a surgeon with extensive experience of this procedure.

2. **Mechanical valves**
   a. **Single-leaflet tilting disk.** This valve (e.g., Björk-Shiley, Medtronic-Hall, and Omniscience) consists of a metallic sewing ring attached to a tilting disk made of pyrolytic carbon that rotates about an off-centered pivot axis, with a range of about 60° to 85° from the occluded to the open position. When open, the prosthesis has two orifices separated by the occluder. The major orifice is formed as the disk swings downstream to the open position. The disk on the other side of the pivot axis swings proximally, forming the minor orifice.
   b. **Bileaflet tilting disk.** The St. Jude and CarboMedics valves have two semicircular pyrolytic carbon disks that rotate freely through 75° to 90°. Two large lateral orifices and a small central rectangular space are created in the open position. A built-in leakage volume is designed to reduce thrombus formation on disks.
   c. **Caged ball.** The Starr-Edwards valve consists of a silicone ball within a cage attached to a metallic alloy ring. The ball is free to travel along the cage over a distance of 1 to 2 cm. Flow across the prosthesis is directed circumferentially around the ball. The hemodynamic profile is less favorable than that of the tilting disk prosthesis. This is the valve with the greatest durability, with a 30-year follow-up in some studies.

B. **Selection of valves.** Table 18.1 summarizes the clinical factors that favor selection of a bioprosthetic versus a mechanical valve. The choice is largely dependent upon the age of the patient at the time of prosthetic valve implantation and on which complication the patient wants to avoid: specifically, anticoagulation therapy and its complications with the mechanical valve and structural valve deterioration with a bioprosthesis.

The recommendation to use tissue valves in older patients and mechanical valves in younger patients is based on information obtained from older trials. There have

TABLE 18.1 Clinical Factors Leading to Selection of a Bioprosthetic versus a Mechanical Valve

Factors favoring bioprosthesis	Factors favoring aortic homograft	Factors favoring mechanical prosthesis
Age > 70 y	Endocarditis	Age < 50 y
Bleeding diathesis	Small aortic annulus in older patients	Combined multivalvular placement
High risk of trauma		Other indications for chronic anticoagulation
Poor compliance		Completed childbearing in younger woman
Young woman considering pregnancy		

TABLE 18.2 Characteristics Favoring Valve Repair versus Replacement

Favoring valve replacement	Favoring valve repair
Rheumatic valve disease	Mitral valve prolapse
Endocarditis	Excessive leaflet mobility
Inexperienced surgeon	Ischemic mitral valve regurgitation
Complex mitral valve morphology	Bicuspid aortic valve with prolapse
Calcified and fibrosed valve	Annular dilatation with normal leaflets
Extensive leaflet destruction	

been no randomized controlled trials after 1982 comparing mechanical with bioprosthetic valves, which makes the decision difficult, as newer bioprosthetic valves may be more durable than older ones. There has been a shift toward using bioprosthetic valves in younger patients over the last decade.

1. **Valve repair.** The feasibility of native valve repair instead of replacement should always be considered prior to surgery (Table 18.2). Currently, the greatest experience is with mitral valve repair. If feasible, mitral valve repair offers several potential advantages over replacement, including **preservation of LV function via conservation of the subvalvular apparatus, lower operative mortality, higher long-term survival rate, and freedom from anticoagulation**. Mitral valve repair may be considered for asymptomatic patients with severe mitral regurgitation if there is a high chance of repair at high-volume centers.

   An aortic valve with predominant regurgitation due to prolapse, but without severe stenosis or calcification, can also be repaired. Intraoperative transesophageal echocardiography (TEE) appears to have a role determining the quality of the repair and predicting the long-term durability.
2. **Bioprosthetic valves** are indicated in patients with **a contraindication to chronic anticoagulation** and are preferred for **patients ≥65 years (70 years in the mitral position)** due to reasonable durability, favorable hemodynamic profile, and freedom from chronic anticoagulation. Approximately 30% of heterograft bioprostheses fail within 10 to 15 years of implantation, although the incidence of bioprosthesis failure is age dependent (Table 18.3). Overall complication rates for aortic bioprosthetic and mechanical valves are similar at 12 years, with a higher rate of reoperation for bioprosthetic valves and a higher rate of hemorrhage with mechanical valves. The advent of newer low-profile bioprostheses and the apparent improved durability of later models have led to an increase in their use, especially in patients who wish to avoid anticoagulation.
3. **Transcatheter aortic valve replacement**, as mentioned before, is now indicated in patients with severe aortic stenosis who are considered inoperable or high risk for conventional open heart surgery due to advanced comorbidities. A comprehensive evaluation for procedural eligibility and candidacy is required including coronary angiography to exclude significant coronary artery disease. If significant coronary lesions are present, they should be revascularized percutaneously and the TAVR procedure is usually deferred for ≥1 month. Computed tomography (CT) angiography with three-dimensional vessel reconstruction is also required to determine the suitability of the iliofemoral access. Dedicated imaging, in particular of the infrarenal aortic segment to the femoral arteries, is needed for sizing of the arterial access (preferably > 6 mm in diameter), vessel tortuosity, and calcification of the iliac arteries. Lastly, TEE, both preprocedural and intraprocedural,

TABLE 18.3 Heterograft Valve Failure Rate 10 Years after Valve Replacement Relative to the Patient's Age

Patient's age (years)	Failure rate at 10 years (%)
< 40	40
40–49	30
50–59	20
60–69	15
≥70	10

Modified from Vongpatanasin W, Hillis LD, Lange RA. Prosthetic heart valves. *N Engl J Med.* 1996;335:412, by permission of the Massachusetts Medical Society.

is important in the evaluation of the aortic annulus size, aortic valve morphology, and calcification of the aortic root and aortic valve leaflets. It can enhance procedural success in determining appropriate valve and device sizing selection in addition to continuous monitoring for procedural complications.

The transapical approach requires a small left thoracotomy to allow direct puncture and sheath introduction into the left ventricle for antegrade delivery of the TAVR system. Patients who require this approach have a higher incidence of peripheral vascular disease, which is a marker of worse long-term outcome. Nonetheless, in patients who require AVR but have aortic atheroma or peripheral vascular disease that limits their candidacy for retrograde transcatheter AVR, the transapical approach should be considered.

4. **Homografts.** The homograft is the **valve of choice in aortic valve endocarditis** and has the lowest valvular gradient among the bioprosthetic valves. Durability was thought to be superior to that of heterografts, but recent studies throw some doubt on this. Only 10% are still functioning after 20 years. The primary operation is more difficult with homografts, as the coronary arteries require implantation. Reoperation is also more complex, as the homograft frequently calcifies and is difficult to remove and replace. The main current indication for an aortic homograft is complex endocarditis involving a native valve, especially in prosthetic valve endocarditis and abscess where the risk of reinfection of a new prosthesis is high. Another indication is in older patients with small aortic root and LVOT in order to maximize hemodynamics and minimize the transaortic gradient.
5. **Mechanical valves.** Mechanical valves are **more durable than bioprosthetic valves**; some can last > 20 years. Mechanical prostheses are generally recommended for **patients < 50 years** because of greater durability and for **patients already on permanent anticoagulation** for previous stroke or arrhythmia. The stroke risk of about 1% per annum for patients with a mechanical valve receiving appropriate anticoagulation management is similar to that for a bioprosthetic valve without anticoagulation. In **younger patients requiring combined aortic and mitral valve replacement**, mechanical valves are preferred, given the more rapid rate of prosthesis deterioration in the mitral position. **Pregnancy should be discouraged in patients with mechanical prostheses** because of the high risk to the mother and the fetus (see Chapter 38). Given their lower profile, mechanical prostheses may be preferred in **patients with small ventricles**. Issues of **compliance with anticoagulation and risks of trauma** should be integrated into the selection of a mechanical valve.

a. St. Jude Medical and Medtronic-Hall valves are the most popular prosthetic valves because of their favorable hemodynamic performance, longevity, and low rates of complications. Loss of structural integrity has been reported in a small percentage of patients with St. Jude valves, whereas the primary concern with the Medtronic-Hall valve is the potential for occluder impingement during placement.

b. Starr-Edwards valves are the most durable of all the prosthetic valves. However, they are less popular today because of their thrombogenicity and suboptimal hemodynamic performance in comparison with tilting disk valves.

c. Manufacture of the Björk-Shiley valve was discontinued in 1986 following published reports of complications with **strut fracture**.

6. The decision with regard to the optimal valve type should be made in consultation with the cardiothoracic surgeon and patient and should not solely be based on age. Lifestyle, compliance, other medical issues, and consideration of pregnancy all have an impact on the decision.

C. Follow-up after valve surgery. There is a **wide spectrum of clinical practices** in the follow-up of the asymptomatic patient after valve surgery. A **Doppler** study should be performed between 1 and 6 weeks following surgery as a baseline for future reference. For **mechanical valves, anticoagulation** should be monitored regularly for life. **Endocarditis prophylaxis** is imperative for prosthetic valves, and patients should receive appropriate education. Annual or biannual echocardiography seems prudent **after the fifth postoperative year** for valve repair and replacement.

D. Anticoagulation. Table 18.4 summarizes the recommended targets for anticoagulation therapy in patients with prosthetic heart valves. The **embolic event rate is greater for mitral than for aortic** prostheses.

1. **Immediate postoperative period**

a. **Mechanical valves.** The approach to **postoperative anticoagulation** for mechanical prostheses varies widely. Early anticoagulation increases the risk of bleeding and tamponade. One approach is **warfarin, but not heparin, 3 to 4 days following surgery** when the epicardial wires are removed. Other centers recommend **low-dose intravenous heparin**, targeted for upper normal limits of activated partial thromboplastin time within 6 to 12 hours after valve replacement, and **full-dose intravenous heparin once the chest tubes are removed**. **Warfarin** is initiated within 24 to 48 hours following valve replacement. **Chronic anticoagulation for mechanical valves is associated with rates** of minor hemorrhage of 2% to 4% per year, major hemorrhage of

TABLE 18.4 Recommended Anticoagulation Therapy for Patients with Mechanical Prosthetic Valves

Level of risk	Prosthesis type	Recommended INR
Low	Single-tilting disk	3.0–4.0
	Double-tilting disk	2.5–3.0
High[a]	Caged disk	3.0–4.5
	Caged ball	3.0–4.5
	Multiple prostheses	3.0–4.5

INR, international normalized ratio.
[a]Patients with atrial fibrillation, left atrial thrombus, severe left ventricular dysfunction, or previous embolic events.

1% to 2% per year, and death of 0.2% to 0.5% per year. The bleeding risk is 5% to 6% in patients aged ≥70 years. The target international normalized ratio (INR) is between 2.0 and 3.0 for mechanical valves (tilting disk and bileaflet) in the aortic position and 2.5 and 3.5 for mechanical valves in the mitral position. Patient-related risk factors for thromboembolism are older age, atrial fibrillation, and LV dysfunction.

b. **Bioprosthetic valves.** The **need for anticoagulation** in bioprosthetic valves is **controversial and is not evidence based**. The risk of embolism is greatest in the early postoperative period, declines after 3 months, and is greater for mitral (7%) than for aortic valves (3%). A reasonable approach is to anticoagulate patients with a **mitral** bioprosthesis for 3 months and then change to aspirin, 325 mg daily. Patients with **aortic prostheses** should receive aspirin, 81 mg daily, for at least 3 months unless there is another reason for anticoagulation. **Patients with prior embolic events, atrial fibrillation, or LV dysfunction should be anticoagulated for the long term**.

2. **Management of anticoagulation in patients with prosthetic valves undergoing noncardiac surgery.** Although the risk of thromboembolism increases when anticoagulant therapy is briefly discontinued, the decision to suspend therapy should be individualized.

   a. For **major procedures** in which substantial blood loss is expected, **warfarin should be discontinued at least 3 days prior to the procedure** to achieve an INR of 1.6 or less. Hospital admission for **intravenous heparin administration** is often recommended for patients with **caged ball prosthetic valves, atrial fibrillation, left atrial thrombus, severe LV dysfunction, or previous embolization. Postoperatively**, intravenous heparin therapy should be **resumed when it is considered safe and continued until therapeutic anticoagulation is achieved with warfarin. Low-molecular-weight heparin (LMWH) may be considered for patients with prosthetic valves as bridge therapy**.

   b. For **minor procedures** (e.g., dental extraction) where blood loss is minimal, anticoagulation can be continued.

3. **Pregnancy** (see Chapter 38). Pregnant women have an increased incidence of thromboembolic complications. The use of warfarin through the entire course of pregnancy is associated with warfarin embryopathy in as many as 6.4% of live births. Given its teratogenic effects, **warfarin should be discontinued (at least between 6 and 12 weeks of the pregnancy) when pregnancy is considered or detected during the first trimester. Subcutaneous heparin** 17,500 to 20,000 U every 12 hours with a target-activated partial thromboplastin time of 1.5 to 2.0 times the control 6 hours after injection should be administered until at least between 6 and 12 weeks of pregnancy, at which time warfarin may be resumed and continued until the middle third trimester. Subcutaneous heparin 5,000 U is then administered twice a day until delivery. Low-dose aspirin can be used in conjunction with anticoagulant therapy for women at higher risk for thromboembolism. LMWH or unfractionated heparin may be considered as an alternative for the entire course of the pregnancy. With LMWH, the anti-Xa levels should be monitored to ensure therapeutic efficacy.

II. ASSESSMENT OF PROSTHETIC VALVES

A. **Clinical presentation.** The clinical presentations of prosthetic valve dysfunction can vary substantially. A discussion of the various entities is detailed in Section **III**.

1. **History.** This should include a thorough cardiovascular review in addition to questions pertinent to the function of the prosthesis.

   a. The **indication** for placement of valve prosthesis, **position** of implantation, **type** of prosthesis, and the **year of implantation** should be elicited. The

model and size of the prosthesis can be verified by the identification card provided by the manufacturer.

b. Other important questions involve **compliance with the anticoagulation** regimen, previous **endocarditis, thromboembolism, fever**, and perceived **change in the quality of the valvular click**.

2. Physical findings

a. The physical examination may be remarkable for a **new murmur, muffled prosthetic valve sounds, or evidence of embolic events**.

b. Prosthetic valves are associated with **distinct auscultatory events caused by prosthesis motion or altered flow patterns**. The prosthesis sounds may mask the normal heart sounds; significant valvular dysfunction may occur without audible changes. However, familiarity with the normal auscultatory findings in the prosthetic valve examination can provide valuable clues on prosthesis dysfunction prior to the more definitive imaging examination. Figure 18.3 summarizes the acoustic characteristics of common valve prostheses.

B. Laboratory examination and diagnostic testing. The diagnosis of structural valve degeneration relies predominantly on echocardiographic findings, which can often identify degeneration prior to the onset of symptoms.

1. Two-dimensional echocardiography. Echocardiography of prosthetic heart valves is more demanding, both to perform and to interpret, compared with the assessment of native valves. By their design, almost all replacement valves are obstructive compared with normal native valves. The degree of obstruction varies with the type and size of the valve. Thus, it may be difficult to differentiate obstructive hemodynamics due to valve design from those of mild obstruction observed with pathologic changes and from prosthesis–patient mismatch. Most

Type of valve	Aortic Prosthesis		Mitral Prosthesis	
	Normal findings	Abnormal findings	Normal findings	Abnormal findings
Caged ball (Starr-Edwards)		Aortic diastolic murmur Decreased intensity of opening or closing click		Low-frequency apical diastolic murmur High-frequency holosystolic murmur
Single tilting disk (Björk-Shiley or Medtronic-Hall)		Decreased intensity of closing click		High-frequency holosystolic murmur Decreased intensity of closing click
Bileaflet tilting disk (St. Jude Medical)		Aortic diastolic murmur Decreased intensity of closing click		High-frequency holosystolic murmur Decreased intensity of closing click
Heterograft bioprosthesis (Hancock or Carpentier-Edwards)		Aortic diastolic murmur		High-frequency holosystolic murmur

FIGURE 18.3 Acoustic characteristics of various mechanical and bioprosthetic valves. (From Vongpatanasin W, Hillis LD, Lange RA. Prosthetic heart valves. *N Engl J Med.* 1996;335:410, with permission from the Massachusetts Medical Society.)

mechanical valves and many biologic valves are associated with trivial or mild transprosthetic regurgitation. The pattern of this "physiologic" regurgitation varies with the design of the replacement valve. Last, because of shielding and artifacts, insonation of the valve, particularly of regurgitant jets associated with the valve, may be difficult.

The interrogation of the prosthetic valve requires a thorough evaluation of the native structures and a systematic approach to the following: prosthetic apparatus, peak and mean gradient, and regurgitant flow. Typically, **TEE** is performed to evaluate **patients whose disease is symptomatic or who are suspected of having endocarditis**. The two-dimensional assessment of prosthetic valves is similar to that of the native valve but is **limited by reverberation artifacts and acoustic shadowing**. In general, echocardiographic evaluation should be done to assess the following:

a. **Occluders and leaflets.** Failure of the leaflet or occluder to open or coapt properly may result from pannus ingrowth (see Section **III.H**), **thrombus formation** (see Section **III.E**), **or calcification of bioprosthetic leaflets**. Imaging of leaflets and occluders may be suboptimal with transthoracic echocardiography (TTE). Multiplane TEE provides higher temporal and spatial resolution of the prosthesis than TTE and may allow measurement of valve area and mobility. Furthermore, use of real-time biplane imaging can enhance the diagnostic accuracy by providing simultaneous orthogonal imaging planes. Although the aortic prosthesis is less well visualized relative to the mitral prosthesis, TEE still provides a better visual inspection of the posterior aspect of the prosthesis and perivalvular structures than TTE. From 0° to 90° in the lower esophageal position, various aspects of the **mitral prosthesis** can be visualized. The mitral prosthesis can be imaged in cross-sectional view from the transgastric window. Mechanical valve leaflets in the aortic position can be challenging to assess, especially when there are two mechanical valves.

b. **Sewing ring.** The orientation of the prosthetic valve in the annulus can be variable; however, **excessive motion** ("rocking") of the sewing ring is consistent with **dehiscence of the prosthesis**. Concomitant paravalvular regurgitation can be commonly identified with the use of color Doppler mapping. **Furthermore, adjacent echolucent structures** identified in the evaluation of endocarditis may represent abscess, fistula, or pseudoaneurysm. In general, **flow into an adjacent echolucent space is pathologic**. This may involve any portion of the annulus or the mitral–aortic intervalvular fibrosa.

c. **Three-dimensional echocardiography.** Three-dimensional echocardiography is increasingly useful in the evaluation of prosthetic valves, as it allows improved display of the complex structures involved especially when used with TEE. Occluder motion and the sewing ring are often well evaluated, and the precise location of an abnormality relative to the sewing ring may be optimally demonstrated.

2. **Doppler evaluation.** Doppler evaluation complements the two-dimensional examination and provides a **reliable indirect assessment of the prosthetic valve performance**. Color Doppler is useful in assessing regions of high velocity, proximal flow convergence, and regurgitant jets, whether they are valvular or perivalvular. Pulsed-wave and continuous-wave Doppler are used to assess transvalvular gradients, from which effective valve areas can be derived.

   a. **Imaging planes for TTE.** Prosthetic mitral and aortic regurgitation can be visualized in the **parasternal long- and short-axis views**. Acoustic shadowing from the aortic and mitral prosthesis can interfere with the color Doppler display in the proximal portion of the aortic and mitral regurgitant jets. The apical views allow assessment of transvalvular pressure gradients but may

underestimate the size of the mitral regurgitant jets due to acoustic shadowing. Pulmonary vein flows may not be available for the same reason. **Prosthetic aortic regurgitation** can be characterized from the **apical window**.

b. Imaging planes for TEE. At 40° from the upper esophageal position (cross-sectional view), the origin of the aortic regurgitant jet (intravalvular or perivalvular) can be identified. The extent of the aortic regurgitant jet into the LV cavity with color Doppler can be visualized at 120°. Advancing the probe to the lower esophagus at 0° brings forth the four-chamber view, which allows unimpeded visualization of the mitral regurgitant jet and measurement of transmitral gradients. Color Doppler interrogation of the medial and lateral aspects of the mitral prosthesis can be performed by increasing the array toward 90° while rotating and advancing or pulling back the probe. Continuous-wave Doppler is used to measure the peak velocity across the prosthesis.

(1) Continuous-wave Doppler evaluation of the **aortic valve** may be performed at the lower esophageal level using the pinch maneuver (simultaneous ante- and right lateral flexion of the probe). Inserting the probe into the stomach at 5° to 10° with the probe anteflexed allows visualization of the origin of the mitral regurgitant jet. At 90° to 110°, continuous-wave Doppler evaluation of the aortic valve may be performed by left lateral flexion of the probe. Advancing the probe further to the deep transgastric view at 0° with anteflexion also brings the aortic valve in line for Doppler interrogation.

(2) Continuous-wave Doppler can also be used to assess **mechanical prosthetic regurgitation**. Advantages of continuous-wave Doppler include excellent temporal resolution to allow identification of specific periods in the cardiac cycle and the ability to indicate the severity of a regurgitant jet by its signal intensity. Using two-dimensional or color-flow imaging to guide, continuous-wave Doppler allows interrogation of different parts of the prosthesis and can help to detect eccentric jets. Color Doppler is useful if a view can be obtained where the ultrasound beam can enter the chamber receiving the regurgitant flow without traversing the prosthetic valve.

C. Normal Doppler findings

1. **Prosthetic valve clicks.** The opening and closure of mechanical valve leaflets create a brief intense Doppler signal that appears as a narrow band on the spectral display.
2. **Prosthetic valve velocities/pressure gradients.** The systolic spectral Doppler contour is frequently triangular, with an earlier systolic peak velocity and a higher peak gradient than that of the mean gradient. The expected normal velocities and pressure gradients for commonly used prosthetic valves are shown in Table 18.5. However, there is a large variability in these numbers depending on flow and other factors. Therefore, a postoperative baseline study, usually before hospital discharge, is indicated for patients with prosthetic valves.
3. **Physiologic prosthetic valve regurgitation.** Many prosthetic valves have regurgitant flow characterized by a uniform color without aliasing. For a mechanical prosthesis, the physiologic prosthetic regurgitant flow typically has a regurgitant jet area of < 2 cm^2 and jet length of < 2.5 cm in the mitral position and a jet area of < 1 cm^2 and jet length of < 1.5 cm in the aortic position. **Most tissue valves exhibit minor regurgitant flow (closure volume) early after implantation**.
4. **Assessment of prosthetic valve dysfunction.** Loss of prosthetic valve clicks is a sensitive marker for prosthesis dysfunction.
   a. Prosthetic valve stenosis

TABLE 18.5 Normal Doppler Values of Prosthetic Valves

Prosthetic valve	Peak velocity (m/s)	Mean gradient (mm Hg)
Aortic position		
Starr-Edwards	3.1 ± 0.5	24 ± 4
Björk-Shiley	2.5 ± 0.6	14 ± 5
St. Jude	3.0 ± 0.8	11 ± 6
Medtronic-Hall	2.6 ± 0.3	12 ± 3
Aortic homograft	0.8 ± 0.4	7 ± 3
Hancock	2.4 ± 0.4	11 ± 2
Carpentier-Edwards	2.4 ± 0.5	14 ± 6
Mitral position		
Starr-Edwards	1.8 ± 0.4	5 ± 2
Björk-Shiley	1.6 ± 0.3	5 ± 2
St. Jude	1.6 ± 0.3	5 ± 2
Medtronic-Hall	1.7 ± 0.3	3 ± 1
Hancock	1.5 ± 0.3	4 ± 2
Carpentier-Edwards	1.8 ± 0.2	7 ± 2

Modified from Nottestad SY, Zabalgoitia M. Echocardiographic recognition and quantitation of prosthetic valve dysfunction. In: Otto CM, ed. *The Practice of Clinical Echocardiography.* Philadelphia, PA: WB Saunders; 1997:803.

(1) **Transvalvular gradients.** Assessment of transvalvular gradients is the mainstay of the Doppler evaluation. **Each prosthetic valve is inherently stenotic and thus has a higher than normal peak velocity across it.** The continuous-wave Doppler gradient across the prosthesis obtained within weeks following implantation serves as a control for subsequent evaluations. High gradients may also be obtained in nonobstructive situations, such as high-output states, tachycardia, anemia, severe prosthetic leaks, or the pressure recovery phenomenon. Pressure recovery occurs secondary to flow acceleration through a narrowed orifice, especially with the mechanical bileaflet prosthesis in the aortic position. With this, the highest pressure measured through the prosthesis by Doppler overestimates the true pressure gradient by approximately one-third. With **prosthetic valve stenosis, pressure recovery becomes less evident.**

(2) **Valve area calculations.** Calculation of orifice area in prosthetic valves is difficult given the complexity of the orifice (struts/disks and so forth), especially in mechanical prostheses. The following methods have been used to approximate orifice area:

(a) **Continuity equation.** The continuity equation can be used to estimate the functional orifice area of prosthetic aortic and mitral valves. For calculation of the prosthetic valve area in the aortic position,

$$\text{Area}_{\text{aortic prosthesis}} = (\text{diameter}_{\text{sewing ring}})^2 \times 0.785\ \text{TVI}_{\text{LVOT}}/\text{TVI}_{\text{aortic prosthesis}}$$

where TVI is time–velocity integral and LVOT is left ventricular outflow tract.

The LVOT diameter is replaced by the sewing ring inner diameter in the equation. The aortic prosthesis TVI is determined from continuous-wave Doppler velocity through the prosthesis. LVOT TVI is determined by pulsed-wave Doppler. Mitral valve prosthesis TVI is determined from continuous-wave Doppler. For the mitral position,

$$\text{Area} = (\text{LVOT diameter})^2 \times 0.785 \times \text{TVI}_{\text{LVOT}}/\text{TVI}_{\text{mitral prosthesis}}$$

(3) Pressure half-time (PHT). For a mitral valve prosthesis, the PHT method is useful for assessing prosthetic valvular stenosis. The empirical constant of 220 provides a reasonable approximation for mechanical prosthetic mitral valve area. The PHT method can also determine whether increased velocity is secondary to increased flow or to obstruction. If the peak velocity is increased but the PHT is not prolonged, then the increased velocity is most likely due to increased forward flow. However, PHT may overestimate the area of the mitral prosthesis. Also if there is concomitant more than mild aortic regurgitation, estimation of prosthetic mitral valve area will not be accurate by PHT method.

(4) Dimensionless index. The LVOT and aortic valve prosthesis velocity ratio is possibly the most helpful index for the evaluation of prosthetic valve stenosis, particularly when the valve size is not known. The higher the index, the larger the EOA, and vice versa. A value ≤0.25 suggests prosthesis stenosis:

$$\text{Dimensionless index} = \text{velocity}_{\text{LVOT}}/\text{velocity}_{\text{aortic prosthesis}}$$

(b) Pathologic prosthetic valve regurgitation. The pathologic flow disturbance is **larger and wider than that seen with physiologic regurgitation**. Its **severity can be reliably quantified by TEE**, which can best identify periprosthetic regurgitation. Pathologic regurgitation may be related to a scarred/calcified annulus, with disruption of the sutures securing the valve or a perivalvular abscess with adjacent tissue destruction. Single or multiple jets may be present.

(1) Severe mitral prosthetic regurgitation is suggested by increased peak early diastolic velocity (≥2.5 m/s) and normal mitral inflow PHT (≤150 m/s) (see Chapter 16).

(2) Severe aortic regurgitation is usually present when the PHT ≤250 milliseconds or when flow reversal is detected in the descending aorta (see Chapter 15).

5. Cinefluoroscopy. Cinefluoroscopy is useful for assessing **mechanical prosthetic valves**. The image intensifier is moved to a position with x-rays parallel to the valve ring plane to determine the occluder's excursions in a caged valve. Despite the radiolucency of pyrolytic carbon disk valves, the opening angle can be measured from positioning the image intensifier parallel to the plane of the open leaflets. **The mitral prosthesis is best visualized from the right anterior oblique (RAO) cranial projections. The aortic prosthesis can be viewed from RAO caudal or left anterior oblique cranial projection**.

a. Diminished motion of the disks suggests valve obstruction, whereas excessive rocking of the base ring (i.e., 7° for aortic prosthesis and 11° for mitral prosthesis) suggests partial dehiscence of the valve.

b. In the setting of **suspected strut fracture in a Björk-Shiley valve**, cinefluoroscopy evaluation of the prosthesis is best performed with the tunnel view

profile. Increased incidence of strut fracture has been noted in patients with an opening angle of 70° or more.

6. **Cardiac catheterization**
   a. **Invasive assessment** of the left ventricle can be performed safely in patients with bioprosthetic aortic valves. However, catheter-based evaluation of the mechanical aortic valve must be performed with a transseptal technique in patients with a mechanical prosthesis. It may be necessary for accurate measurement of the prosthetic mitral valve gradient, as catheter-based assessment overestimates the mitral valve gradient because of a dampening of the pressure contour and intrinsic delay in the pulmonary capillary wedge tracing.
   b. **Never cross the following prosthetic valves:**
      (1) Single or bileaflet tilting disk prosthesis
      (2) Caged disk prosthesis
      (3) Caged ball prosthesis
7. **Magnetic resonance imaging** can be performed safely in patients with most prosthetic valves, as they are not ferromagnetic. It can identify **prosthetic regurgitation, periprosthetic fistulas, and abscess**. Prosthetic valves cause **imaging artifacts**, which preclude assessment of the leaflets of the prosthetic valve; however, dedicated sequences can provide information about **blood flow velocities** and **regurgitant jets**.
8. **Multislice** gated cardiac CT with retrospective image acquisition also allows adequate evaluation of leaflet motion in mechanical valves using multiplanar reformatting and reconstruction to view the valve motion in any selected plane. The utility of this method over conventional fluoroscopy remains to be evaluated. One particular limitation compared with cinefluoroscopy is the lower temporal and spatial resolution of CT as well as the need for potentially higher doses of ionizing radiation. However, it can be particularly useful in patients with more than one mechanical valve prosthesis, in which echocardiography can be difficult due to artifacts.

III. VALVE DYSFUNCTION AND COMPLICATIONS RELATED TO PROSTHETIC VALVES

A. Atrial fibrillation. Up to 50% of patients undergoing valve surgery experience postoperative atrial fibrillation. Management of atrial fibrillation is discussed in Chapter 24.

1. In **patients without a previous history** of atrial fibrillation, the **arrhythmia is often self-limited**.
2. For patients with **persistent atrial fibrillation beyond 24 hours, anticoagulation, direct current cardioversion, and a short course of antiarrhythmic therapy** are warranted.
3. β-Blockade or amiodarone prophylaxis has been found to reduce the incidence of postsurgical atrial fibrillation.

B. Conduction disturbances. High-grade heart block requiring permanent pacemaker implantation has been described in 2% to 3% of patients after valve replacement and 8% following repeat valve surgery. It is caused by trauma to the bundle of His or from postoperative edema of the periannular tissue. Aortic or mitral annular calcification, preoperative conduction disturbance, advanced age, infectious endocarditis, and tricuspid valve surgery are associated with higher rates of postoperative conduction abnormalities, leading to permanent pacemaker implantation. As mentioned before, the higher profile of Medtronic's self-expandable CoreValve ReValving system has been associated with higher rates (up to 25%) of complete heart block requiring permanent pacemaker implant.

C. Endocarditis. Approximately 3% to 6% of patients with prosthetic heart valves will experience prosthetic valve endocarditis. Prosthetic valve endocarditis is typically

associated with large vegetations, since microorganisms are sheltered from the host defense mechanisms.

1. Early prosthetic valve endocarditis (< 60 days following implantation) is typically caused by *Staphylococcus epidermidis.* The clinical course is often fulminant, with high mortality rates ranging from 20% to 70%.
2. Late prosthetic valve endocarditis occurs most commonly in patients with multiple prostheses and bioprosthetic valves, especially in the aortic position. Its clinical course resembles that of native valve endocarditis. Streptococci are the most common infectious agents, followed by gram-negative bacteria, enterococci, and *S. epidermidis.*
3. TEE is the imaging modality of choice, with sensitivity of 95% and specificity of 90% in diagnosis. It is also useful in detecting complications including abscess, tissue invasion, dehiscence, and fistula formation and monitoring the efficacy of medical therapy.
4. **Therapy.** The mortality of patients managed with antibiotics alone is 61% versus 38% for those having valve replacement. (See Chapter 19 for more information on diagnosis, management, and antibiotic prophylaxis for endocarditis.)
   a. **Medical therapy.** Medical cure of prosthetic valve endocarditis caused by **staphylococci, gram-negative organisms, or fungi is rare. Streptococcal** prosthetic valve endocarditis responds to medical therapy alone in **50% of cases**. Patients with mechanical prosthetic valve endocarditis should **continue to receive anticoagulation**. In the absence of anticoagulation, prosthetic valve endocarditis is associated with up to 50% incidence of stroke. Continuing anticoagulation for patients with prosthetic valve endocarditis is associated with a 10% incidence of cerebral embolization. There is no conclusive evidence for increased hemorrhage with warfarin in patients with prosthetic valve endocarditis. Careful surveillance of medically managed patients with prosthetic endocarditis is essential and should involve an infectious diseases consultant, multiple repeat cultures after the cessation of antibiotic treatment, and follow-up with TEE when needed. A high index of suspicion should be maintained for the presence of residual infection, and surgical reevaluation should be considered if medical treatment fails.
   b. **Surgical therapy.** Valve replacement surgery is indicated in the setting of
      (1) persistent bacteremia despite intravenous antibiotics
      (2) tissue invasion or fistula formation
      (3) recurrent embolization
      (4) fungal infection
      (5) prosthesis dehiscence or obstruction
      (6) new or worsening heart block
      (7) **new-onset or worsening** congestive heart failure

D. Hemolysis. Subclinical hemolysis is present in many patients with mechanical valves but **rarely results in significant anemia**.

1. **Pathophysiology and etiology.** Clinical hemolysis occurs in 6% to 15% of patients with **caged ball valves** but is uncommon with normal bioprosthetic or tilting disk valves. Clinical hemolysis is also associated with **multiple prosthetic valves, small prostheses, periprosthetic leaks, and prosthetic valve endocarditis**. Mechanisms involved in the generation of hemolysis include high shear stress or turbulence across the prosthesis, interaction with foreign surfaces such as cloth, and rapid deceleration of erythrocytes following collision with adjoining structures (e.g., struts or cardiac walls).
2. **Laboratory examination and diagnostic testing**
   a. Diagnosis is made by **elevated lactate dehydrogenase, reticulocyte count, unconjugated bilirubin, urinary haptoglobin**, and presence of **schistocytes on blood smear**.

b. Echocardiographic findings consistent with mechanical hemolysis include **abnormal rocking of the prosthesis or regurgitant jets of high shear stress** (e.g., eccentric or periprosthetic regurgitant jets or those impacting a solid surface such as the left atrial appendage or sewing ring).

3. Therapy

a. Medical therapy. Mild hemolytic anemia can be managed with **iron, folic acid supplement, erythropoietin stimulants and, if needed, blood transfusion. β-Blockade and blood pressure control** may reduce the severity of hemolysis. Paradoxically, treatment of the anemia may reduce the degree of hemolysis by limiting the need for high flow through the defective valve.

b. Surgical therapy. Repair of perivalvular leaks or valve replacement is indicated in **patients with severe hemolysis requiring repeated transfusions or in those with congestive heart failure**. Increasingly, however, it is possible to reduce focal paravalvular leaks percutaneously with the use of coils or other occluders. Percutaneous approaches are not feasible with extensive dehiscence or where there is active infection.

E. Thrombosis. The annual incidence of mechanical prosthetic valve thrombosis is 0.2% to 1.8%. The incidence is highest in the tricuspid position, followed by the mitral and then the aortic position. Thrombus is suspected in patients with **acute onset of symptoms, embolic event, or inadequate anticoagulation**. Thrombosis at bioprostheses is uncommon but may occur in low-flow or prothrombotic states.

1. Laboratory examination and diagnostic testing. TEE is the most widely used diagnostic technique, although cinefluoroscopy can be used to document restriction in occluder mobility. Three-dimensional TEE may be of particular value in some instances in outlining the nature of the obstruction. No imaging modality, however, can clearly differentiate thrombus from pannus (see Section **III.H**). Frequently they coexist. Comparison with previous studies is crucial to determine temporal changes. Although sometimes differentiation of thrombus versus pannus can be difficult, a few things argue more in favor of pannus such as location (aortic > mitral valve), duration since valve implantation, subacute/chronic course, symmetrical involvement, location of thickening (pannus is usually annular, whereas thrombus is most of the times attached to the valve ring). Subtherapeutic anticoagulation over an extended period increases the likelihood of thrombus. Echocardiographic features suggestive of thrombus include soft, irregular, or mobile mass.

2. Therapy. The valve type or suspected duration of valve thrombosis does not influence the indications for treatment, although location of prosthetic valve does.

a. Priority of therapy

(1) Heparin is typically initiated early in the course of evaluation.

(2) Warfarin is continued unless surgery is planned.

(3) TTE, TEE, or cinefluoroscopy should be performed at 24 hours and, if the thrombus is still present, should be repeated serially.

b. Medical therapy

(1) Fibrinolytic therapy is considered the treatment of choice for **right-sided prosthetic valve thrombosis** because the consequences of distal embolization are less severe than in left-sided prosthesis. Streptokinase and urokinase are the most commonly used agents. Fibrinolytic therapy has an initial success rate of 82%, overall thromboembolism rate of 12%, and a 5% incidence of major bleeding episodes. For left-sided valves, there is a similarly high success rate (82%) with fibrinolytic therapy; however, the associated risks of death (10%) or systemic embolism (12.5%) are high. Thrombolysis should be considered for left-sided valves in patients with contraindications to surgery. Thrombolysis may be a reasonable alternative

to surgery for mitral or aortic prosthetic valve thrombosis in patients with a small thrombus burden, particularly if there is hemodynamic compromise and/or multiple comorbidities increasing the surgical risk.

(a) The classical regimen for **streptokinase** is a 500,000 IU bolus given over 20 minutes, followed by an infusion of 1.5 million IU infused over 10 hours.

(b) rtPA (recombinant tissue plasminogen activator) 10 mg bolus followed by 90 mg an hour for 9 hours.

(c) Thrombolysis should be stopped if there is no hemodynamic improvement after 24 to 72 hours. TEE is useful in assessment of progress.

(d) Following successful thrombolysis, close **follow-up of anticoagulation along with serial Doppler echocardiography** on an individual basis is recommended.

(2) Anticoagulation with heparin and warfarin is generally recommended for **small thrombus** (≤5 mm). The regimen consists of intravenous heparin followed by subcutaneous heparin 17,000 U twice a day and warfarin (INR 2.5 to 3.5) for up to 3 months.

c. Surgical approach. The lowest surgical mortality reported has been approximately 5%. The risk profile of the individual patient must be balanced against the expertise and experience at each center.

(1) Valve replacement and debridement are generally performed for **left-sided prosthetic valve thrombosis**, unless the thrombus is small or the patient has a prohibitive surgical risk.

(2) Surgery is also indicated in the case of **unsuccessful thrombolysis** 24 hours following discontinuation of the infusion.

F. Dehiscence. Detachment of the sewing ring from the annulus may occur in the early postoperative period because of poor surgical techniques, excessive annular calcification, chronic steroid use, fragility of the annular tissue (particularly following prior valve operations), or infection. Late dehiscence occurs mainly from infectious endocarditis. **Abnormal rocking of the prosthesis** on echocardiography or cinefluoroscopy is an **indication for urgent surgery**. Some rocking of a mitral prosthesis may occur normally with preservation of the mitral valve apparatus.

G. Patient–prosthesis mismatch. All prosthetic valves, with the exception of stentless aortic homografts, have effective orifices that are smaller than those of native valves. There is an **inherent pressure gradient and relative stenosis with each prosthesis**. Occasionally, when an inappropriately small prosthesis is placed, the **ensuing low output may cause symptoms**. Patient–prosthesis mismatch should be considered mild if indexed valve EOA is < 0.85 cm^2/m^2, moderate if > 0.65 cm^2/m^2 but ≤ 0.85 cm^2/m^2, or severe if ≥ 0.65 cm^2/m^2. The impact and prevalence of patient–prosthesis mismatch are controversial. Depending on the definition and surgical series used, this mismatch may occur between 20% and 70% of cases after aortic valve replacement. It has been shown in some series to be associated with worse hemodynamic function, less regression of LV hypertrophy, more cardiac events, and lower survival, although others question its importance. Unlike most of the other risk factors, patient–prosthesis mismatch can be avoided or its severity can be more or less reduced by putting in place a prevention strategy at the time of the operation. **It is rare that patient–prosthesis mismatch occurs to a degree that surgical explantation is necessary**.

Some important points to consider:

1. The projected indexed EOA should be systematically calculated at the time of the operation to estimate the risk of patient–prosthesis mismatch.
2. In a patient with a **small annulus, a hemodynamically favorable prosthesis** like a stentless bioprosthesis, aortic homograft, or a tilting disk valve is preferred. Alternatively, the aortic annulus may be enlarged surgically in order to accommodate a prosthesis of acceptable size.

3. Aortic prostheses < 21 mm in diameter are not recommended for a large or physically active patient.
4. Young patients in particular, as well as those with poor LV function and/or severe LV hypertrophy, are more vulnerable to patient–prosthesis mismatch.

H. Pannus formation. Valve obstruction occurs in up to 5% of mechanical valves per year. Valve thrombosis and pannus formation are responsible for the majority of mechanical prosthesis obstructions. Frequently, thrombus coexists with pannus. **Little is known about the causes** of fibroblastic proliferation in pannus formation. Foreign body reactions to the prosthesis, inadequate anticoagulation, endocarditis, and blood flow turbulence in the mitral position have been implicated as potential causes. Pannus formation begins around the annulus of the valve and is more common in aortic than in mitral valve prostheses. A subacute presentation of fatigue or dyspnea in a patient who is well anticoagulated can suggest pannus formation. **TEE and/or cinefluoroscopy is generally required** to identify the cause of prosthetic valve obstruction.

I. Embolic stroke. Following an embolic stroke, the risk of recurrent stroke is approximately 1% per day for the first 2 weeks.

1. If no evidence of hemorrhage is detected on CT scan at 24 to 48 hours, **intravenous heparin** should be administered after a small to moderate embolic stroke. **Maintaining anticoagulation** reduces the risk of recurrent stroke to one-third but **carries an increased risk of hemorrhagic transformation** of 8% to 24%, particularly during the first 48 hours.
2. In patients with **larger infarcts, anticoagulation should be withheld for 5 to 7 days**.
3. Anticoagulation is withheld for 1 to 2 weeks in the setting of **hemorrhagic transformation**.
4. **Aspirin or clopidogrel** may be needed in the event of recurrent strokes, despite adequate anticoagulation.
5. Rarely, **reoperation with placement of a tissue valve** is needed for recurrent embolization.

J. Mechanical failure

1. Failure of **bioprostheses** is expected as the valves age. This may manifest as stenosis, regurgitation, or a combination and is usually due to the deposition of calcium on the leaflets. The onset of mechanical failure is usually gradual. Leaflet tears may produce a sudden clinical deterioration with the onset of severe regurgitation. Bioprosthetic deterioration is managed expectantly with increasing frequency of evaluation as the valve ages and deterioration becomes more evident clinically and on echo. Indications for reoperation are similar to those for native valve lesions, although the threshold to reoperate is somewhat higher, given the greater mortality and morbidity associated with reoperation.
2. Failure of the current generation of **mechanical prostheses** is rare but may precipitate catastrophic hemodynamic compromise. Catastrophic failure occurs when a strut holding the occluder breaks, allowing the occluder to embolize, resulting in overwhelming regurgitation. Strut failure has been reported most commonly with the Björk-Shiley valve and results from fatigue of a metal weld in valves of specific sizes (larger) and valves with year of manufacture 1981 to 1982, especially, in those younger than 50 years at time of implantation. Explantation of those at highest risk has been recommended; in evaluating patients with Björk-Shiley valves, the risk/benefit of explantation versus strut fracture should be determined, based on the excellent published literature on the topic.
3. In older ball-in-cage prostheses, ball **variance**, a structural deterioration of the occluder, can occur, giving rise to impaired occluder motion, sticking, and thromboembolism. This is rarely seen nowadays with improved prosthetic materials.

Brian P. Griffin

Infective Endocarditis

I. INTRODUCTION

A. Infective endocarditis (IE) is **an infection of the cardiac endothelium**, macroscopically seen as vegetations. Despite modern medical and surgical therapy, IE is a serious and life-threatening condition. Mortality rates are 20% to 30% for both native and prosthetic valve endocarditis (PVE) and may be as high as 70% in certain high-risk patients. The clinical diagnosis is based on multiple elements, and **IE is best managed via multidisciplinary collaboration among cardiologists, cardiothoracic surgeons, and infectious disease specialists**.

B. The incidence of IE has remained constant over the last 30 years, accounting for 1 case per 1,000 hospital admissions. An estimated 10,000 to 15,000 new cases of IE are diagnosed each year in the United States, and the incidence has increased in the elderly and in illicit injection drug users. There has also been an increase in the number of acute cases, prosthetic valve infections, and cases due to gram-negative, rickettsial, chlamydial, fungal, and fastidious organisms.

C. Risk factors associated with infection include underlying cardiac structural abnormalities, immunosuppressed status, underlying conditions that predispose patients to pacemaker-related infections, prolonged surgery, reoperation, catheter-related bacteremia, and sternal wound infection.

II. CLINICAL PRESENTATION

A. Signs and symptoms. The clinical manifestations of IE are highly variable, ranging from subtle symptoms to fulminant congestive heart failure (CHF) with severe valvular regurgitation. **Acute IE** presents as marked toxicity and progresses to valvular destruction and metastatic infection over several days to weeks. **Subacute IE** evolves over several weeks to months with mild or modest toxicity and rarely causes metastatic infection. The rate of progression depends upon the virulence of the causative organism, the age and underlying health of the patient, and the nature and extent of the underlying valvular disease.

1. The **hallmarks of IE are fever and a new murmur** (> 85%); however, fever may be absent in patients who are elderly, uremic, or immunosuppressed. Murmurs may be absent with right-sided or mural infection or intracardiac device infections.
2. The patient often has nonspecific symptoms of fatigue, weight loss, malaise, chills, night sweats, and/or musculoskeletal aches.

B. Physical findings. A new murmur remains an important finding.

1. CHF occurs in up to 55% of cases and tends to be more common in those with aortic valve disease (75%) than in those with mitral (50%) or tricuspid (20%) valve involvement.
2. Neurologic findings may include clinically apparent cerebral emboli (20%), encephalopathy (10%), mycotic aneurysm leak (< 5%), meningitis, or brain abscess (< 5%).

3. Additional physical findings reflecting **embolic or immune complex phenomena** include mucosal **petechiae** (20% to 40%), **splinter hemorrhages** (subungual dark linear streaks: 10% to 30%), **Osler's nodes** (painful, tender erythematous nodules on the pads of fingers or toes: 10% to 25%), **Janeway lesions** (erythematous, macular, nontender lesions on the fingers, palms, or soles: < 5%), **clubbing** (10% to 20%), **arterial embolism** (peripherally or centrally), **splenomegaly** (30% to 50%), and **Roth's spots** (retinal hemorrhages: < 5%). These classic physical findings are **neither sensitive nor specific** for the diagnosis of IE, and their frequency is continuing to diminish due to a decrease in *Streptococcus* viridans IE and an increase in *Staphylococcus aureus* IE.
4. A formal **fundoscopic examination** should be routine in all patients with suspected or documented IE. It may reveal **chorioretinitis or endophthalmitis**.
5. **Systemic** embolization occurs in 25% to 50% of cases of IE and may mimic acute coronary syndrome (coronary artery emboli), peritonitis (embolization to the spleen, kidney, or bowel), acute stroke (cerebral emboli), and pulmonary embolism (from right-sided IE) or cause a cold extremity with reduced or absent pulse. Septic emboli also cause Janeway lesions.

III. ETIOLOGY

Table 19.1 presents the various etiologic factors.

A. Seventy percent to 75% of patients with IE have preexisting cardiac abnormalities. Mitral valve prolapse with regurgitation is the leading condition underlying IE in adults. Rheumatic heart disease as a substrate for IE is decreasing, with congenital heart disease underlying 10% to 20% of IE cases.

B. The source of infection can only be identified occasionally (e.g., dental procedures, an infected vascular catheter, or an infected skin lesion). In many patients, there is no history of an antecedent localized infection.

C. Native valve endocarditis

1. The most common microorganisms that cause native valve IE in adults are streptococcal and staphylococcal organisms (80%). Other important causes

TABLE 19.1 Frequency of Organisms Causing Infective Endocarditis

Organism	NVE (%)	IDU (%)	Early PVE (%)	Late PVE (%)
Streptococci	60	15–25	5	35
Viridans *Streptococcus*	30–40	5–10	< 5	25
S. bovis	10	< 5	< 5	< 5
Enterococci	10	10	< 5	< 5
Staphylococci	25	50	50	30
Coagulase positive	23	50	20	10
Coagulase negative	< 5	<5	30	20
Gram-negative (aerobes)	< 5	5	20	10
Fungi	< 5	< 5	10	5
Culture negative	5–10	< 5	< 5	< 5

IDU, intravenous drug use; NVE, native valve endocarditis; PVE, prosthetic valve endocarditis.

Adapted from Fuster V, Alexander RW, O'Rourke RA, eds. *Hurst's the Heart*. 11th ed. New York, NY: McGraw Hill; 2004.

include *Streptococcus bovis*, *Enterococcus*, and the HACEK (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*) group organisms. The HACEK group, accounting for roughly 3% of cases, includes fastidious gram-negative organisms that are normal flora in the upper respiratory tract. *S. bovis* IE is often associated with colonic polyps and colon cancer; as such, a colonoscopy is recommended for these patients.

2. Right-sided IE in injection drug users is usually due to *S. aureus* (60%), with a predilection for normal as well as abnormal cardiac valves. Despite the virulence of this organism, the disease tends to be **less severe** (mortality rates of 2% to 6%) than with left-sided IE. The valve most commonly affected in injection drug users is the tricuspid valve (60% to 70% of cases), followed by the mitral (30% to 40%) and the aortic valves (5% to 10%). More than one valve is involved in 20% of these patients. Septic pulmonary emboli occur in up to 75% of injection drug users with tricuspid IE.
3. IE from *Pseudomonas aeruginosa* is both **destructive and poorly responsive to antibiotic therapy and thus often necessitates surgical intervention**.
4. Enterococcal IE is increasing in prevalence. The diagnosis must be considered in patients who have undergone recent genitourinary or obstetric procedures; these patients may not have underlying heart disease.
5. Other members of the Enterobacteriaceae (*Escherichia coli, Salmonella*, *Klebsiella*, *Enterobacter*, *Proteus*, *Serratia*, *Citrobacter*, *Shigella*, and *Yersinia*) are occasionally implicated in IE.
6. *Streptococcus pneumoniae* accounts for 1% to 3% of native valve IE, and it may present as part of the **"Osler triad,"** which also includes pneumococcal pneumonia and meningitis. Alcoholics are typically affected, and the mortality rate is high (30% to 50%).
7. The most common congenital heart anomalies predisposing to IE are bicuspid aortic valve, patent ductus arteriosus, ventricular septal defect, coarctation of the aorta, and tetralogy of Fallot. There is **no evidence** that secundum atrial septal defects increase the risk of IE.
8. *Staphylococcus lugdunensis* is a rare but destructive cause of IE. This organism is a coagulase-negative *Staphyloccus*; however, it differs from other coagulase-negative staphylococci in its aggressive nature and predilection for native valves. *S. lugdunensis* IE portends a high complication and mortality rate without surgical intervention.

D. PVE accounts for about 10% to 20% of all cases of IE. The greatest risk of infection is in the first 6 months after valve implantation and appears to be **similar in mechanical and bioprosthetic valves**. Recent studies have suggested that infection occurs with similar frequencies at the mitral and aortic positions.

1. PVE occurring within 2 months of surgery (early PVE) is commonly associated with intraoperative contamination and nosocomial infection and this usually implicates **coagulase-negative staphylococci** (30% of cases). The second most common pathogen in early PVE is *S. aureus* (20% of cases).
2. The microbiology of PVE with an onset of more than 2 months after surgery (late PVE) reflects the pathogens of native valve IE and is most commonly caused by streptococcal species, *S. aureus*, and *Enterococcus*. Coagulase-negative staphylococci cause < 20% of infections in this period. Fungi account for 10% to 15% of late PVE cases and are associated with a higher mortality rate. Among 270 cases of fungal endocarditis reported from 1965 to 1995, 135 (50%) occurred on prosthetic valves. These patients generally lacked an identifiable portal of entry for fungemia. Establishing the diagnosis of fungal PVE can be difficult due to the low yield from blood cultures. Despite aggressive antifungal therapy, these patients remain at risk for the development of PVE months or years later. *Corynebacterium* species and other coryneform bacteria, often called

diphtheroids, are also an important cause of PVE during the first year after surgery (5%). Although they are often blood culture contaminants, diphtheroids in multiple cultures should not be ignored.

E. Pacemaker/defibrillator endocarditis is increasing in frequency in clinical practice with the burgeoning number of devices being implanted. The incidence of endocarditis following device therapy ranges from 0.2% to 7%. The infection may involve the generator or defibrillator pocket, the electrodes, and valvular or nonvalvular endocardium.

1. Pacemaker/defibrillator endocarditis occurring within 1 to 2 months of surgery is likely caused by direct intraoperative microbial seeding. Late infection in the pocket produces a thinning of the overlying tissue and ultimately device erosion. The infection may eventually involve the electrodes and ultimately the endocardium. Hematogenous dissemination from distant sites of infection appears to be relatively rare, with the exception of *S. aureus* bacteremia.

2. The majority of infections in PVE are caused by staphylococci: *S. aureus* and coagulase-negative staphylococci. More than 90% of early infections are caused by coagulase-negative staphylococci, whereas late infections are caused by both *S. aureus* (50%) and coagulase-negative staphylococci (50%). Infection by gram-negative bacilli, enterococci, or fungi is rare.

F. The incidence of **culture-negative endocarditis** may be as high as 10%. Blood culture–negative endocarditis is defined as endocarditis without positive cultures after inoculation of three blood samples. Cultures can be negative in IE when there is infection with a fastidious bacteria or fungus, the microbiological techniques are inadequate, or there had been administration of antibiotic therapy prior to obtaining blood cultures. The latter reason is the most common cause of culture-negative IE, and the most common causative agents are *Streptococcus* or fastidious organisms such as fungi, HACEK organisms, anaerobes, *Legionella*, *Chlamydia psittaci*, *Coxiella*, *Brucella*, *Bartonella*, *Tropheryma whipplei*, and nutritionally deficient streptococci. *Bartonella henselae* infection is a rare cause of subacute IE, which is associated with exposure to cats. *Coxiella burnetii* causes Q fever and often infects previously damaged valves or prosthetic valves. *T. whipplei* is the cause of Whipple's disease, and this organism can be identified using periodic acid-Schiff staining of macrophages or polymerase chain reaction (PCR). **Nonbacterial endocarditis** (Libman-Sachs, marantic, and antiphospholipid syndrome) should also be considered in cases of culture-negative IE.

G. Fungal endocarditis (*Candida* and *Aspergillus*) usually occurs in association with **prosthetic valves, indwelling intravascular hardware, immunosuppression, or injection drug use. The most common cause is** Candida **species, but other causes include *Histoplasma* and *Aspergillus*. Fungal IE usually presents with large vegetations that extend into the perivalvular apparatus and embolize into large vessels and therefore requires surgical intervention**.

IV. PATHOPHYSIOLOGY.

The first step in the pathogenesis of vegetation is the formation of a **nonbacterial thrombotic endocarditis (NBTE)**, which usually results from endothelial injury followed by focal adherence of platelets and fibrin. Microorganisms circulating in the bloodstream in turn infect this sterile platelet–fibrin nidus.

A. Vegetations classically occur along the line of closure of the valve leaflet. The endothelium may be injured by regurgitant jets, leading to vegetation formation on the atrial surface of incompetent atrioventricular valves or the ventricular surface of incompetent semilunar valves. The foreign body, such as an intracardiac device, is not endothelialized initially and acts as a formation site for platelet–fibrin thrombi.

B. Bacteremia is the event that converts NBTE to IE when host defenses fail. The foreign material also impairs host defenses, rendering them more difficult to treat.

C. Vegetations often further impair valvular coaptation or cause perforation or chordal rupture, leading to worsening of regurgitation and CHF. Furthermore, the vegetations may dislodge, causing peripheral septic–nonseptic embolization.

D. The infection may extend to the surrounding structures, such as the valve ring, the cardiac conduction system, the adjacent myocardium, or the mitral–aortic intravalvular fibrosa. Consequently, conduction defects, abscesses, diverticula, aneurysms, or fistula may develop. Infections involving prosthetic valves commonly invade paravalvular tissue, resulting in abscess formation or valve dehiscence.

V. LABORATORY EXAMINATION

A. Blood tests

1. Laboratory findings often reflect nonspecific acute inflammatory response, manifest as a **modest leukocytosis**, a **normochromic normocytic anemia**, and a slightly increased or decreased **platelet count**. Other laboratory abnormalities may include an **elevated erythrocyte sedimentation rate**, C-reactive protein, rheumatoid factor, and/or a hypergammaglobulinemia. IE may also cause false-positive Venereal Disease Research Laboratory (VDRL) test and Lyme serologic test.

2. Decreased complement and an elevated blood urea nitrogen or creatinine may implicate renal dysfunction from an immune complex glomerulonephritis or drug toxicity.

3. Blood cultures are critical in the diagnosis and management of IE. However, if a patient is acutely ill, **therapy should not be delayed for more than 2 to 3 hours**, as a fulminant infection may be rapidly fatal. In recent reports, cultures were negative in 2% to 7% of cases with established IE, despite the best modern methods.

a. If the clinical condition allows, three sets of cultures should be drawn at three different venipuncture sites before empiric antimicrobial therapy is started. Each set should include two flasks, one containing an aerobic medium and the other an anaerobic medium, into which at least **20 cm^3** (per tube) of blood should be placed. The HACEK group bacteria are cultured routinely. Fungal cultures should be included when fungal infection is suspected, such as in immunocompromised hosts.

b. Intravascular infection leads to constant bacteremia originating from vegetations. Therefore, **it is unnecessary to await the arrival of a fever spike or chills to obtain blood cultures**.

c. The laboratory should be alerted if a **culture-negative IE or a fastidious infectious agent** is suspected, as it may be necessary to enhance the culture medium or prolong the incubation period. For example, the HACEK group (see Section **III.C.1**) needs prolonged incubation of up to 21 days. The most common culture-negative IE organisms are *C. burnetii*, *Bartonella* sp., *T. whipplei*, HACEK group bacteria, *Brucella* sp., *Legionella* sp., *Mycoplasma* sp., *Mycobacterium*, and fungi. Serology for *Brucella*, *Legionella*, *Coxiella*, or *Psittacosis* may be revealing. Fastidious organisms can also be identified using PCR in valvular specimens. This technique does not require a culture medium; however, it does require excised valvular tissue. PCR has been shown to have a sensitivity of 41% and a specificity of 100% in recent studies, and thus it may provide important information about the causes of IE that could not be identified by culture. This information may help guide future empiric treatment plans in certain patient populations.

d. Special attention should be paid to cultures positive for coagulase-negative staphylococci. *S. lugdunensis* is a coagulase-negative Staphylococcus that rarely causes IE. Unlike other coagulase-negative staphylococci it often affects native valves, is destructive, frequently causes abscesses, and is associated with high mortality without surgical intervention. Thus, in the setting of

high suspicion for IE, cultures positive for coagulase-negative staphylocccci should not be disregarded as a contaminant and should be further speciated.

B. Histologic evaluation. Histopathology of resected valvular tissues remains the gold standard for the diagnosis of IE. It may demonstrate valvular inflammation, vegetations, and/or specific organisms. Detection of an etiologic agent in the vegetation using special stains or immunohistology can guide the choice of antimicrobial treatment. This is particularly useful in culture-negative IE, such as Q fever, *Bartonella* spp., or *T. whipplei* (Whipple's disease bacillus). **Good communication among cardiologists, surgeons, pathologists, and microbiologists helps ensure accurate diagnosis**.

C. Urinalysis. Microhematuria with or without proteinuria may be seen.

D. Electrocardiography. All patients with suspected IE should undergo baseline and follow-up electrocardiogram (ECG).

1. ECG may reveal **conduction disturbances** reflecting intramyocardial extension of infection, ranging from a prolonged PR interval to complete heart block (especially with PVE). A **new atrioventricular block** carries a 77% positive predictive value for abscess formation with 42% sensitivity.
2. Myocardial infarction due to embolization of vegetations occurs rarely.

E. Chest x-ray may reveal **CHF or pleural effusions.** Right-sided IE may cause **nonspecific infiltrates** due to multiple septic pulmonary emboli.

VI. DIAGNOSTIC IMAGING TECHNIQUES

A. Echocardiography has a key role in both diagnosis and management of IE. The primary objective is to identify, localize, and characterize valvular vegetations and their effects on cardiac function. Vegetations may occur at intracardiac locations other than valves, such as the site of impact of a high-velocity jet or shunt. A limitation of echocardiography is that vegetations cannot always be distinguished from other noninfectious masses.

1. All patients in whom IE is suspected should undergo baseline transthoracic echocardiography (TTE) to define underlying cardiac abnormalities, to determine the size and location of vegetations, and to explore the possibility of complications (e.g., aortic annular ring abscess). TTE has a low sensitivity for vegetations in IE (29% to 63%) but has close to 100% specificity. However, the finding of morphologically and functionally normal valves on TTE decreases the likelihood of IE. In one series, 96% of patients with normal valves on TTE also had a negative transesophageal echocardiography (TEE).
2. TEE has increased the diagnostic accuracy of IE. If IE is strongly suspected and the TTE is negative, then TEE should be performed because it is more sensitive in detecting vegetations, especially if TTE imaging is difficult. TEE is particularly useful for assessing posterior structures, abscesses, fistulae, perivalvular leaks, small vegetations, right-sided heart structures, masses on intracardiac devices, leaflet perforations, and prosthetic valves. The ability to detect paravalvular abscesses, fistulae, and paraprosthetic leaks has a major impact on management strategy. Intraoperative TEE can be used to evaluate the success of surgical interventions and the need for potential modification of reparative cardiac surgical procedures. A postoperative TTE should also be done as a baseline measure of cardiac anatomy/function for long-term follow-up. Although in most cases a TTE should be the first diagnostic test of choice, in certain circumstances TEE may be the optimal initial test to rule out IE. These include cases that involve *S. aureus* bacteremia, prosthetic valves, prior IE, limited echo windows, and bacteremia due to an organism that is known to commonly cause IE.
   a. A negative result on TEE indicates a low likelihood of IE (provided adequate images are available). However, it does not completely rule out the diagnosis. The negative predictive value is > 90%, but false negatives may occur early

in endocarditis or if vegetations are small. Repeat TEE should be considered if clinical suspicion is high. Of note, a negative TEE should never override strong clinical evidence of endocarditis in the diagnosis of PVE.

b. Myocardial abscesses are more reliably detected with TEE (87% sensitive) than with TTE (28% sensitive). Detection of a perivalvular abscess is essential, as an abscess is a serious complication and a strong indication for surgical intervention.

c. In the setting of PVE, TEE is superior (82% sensitive) to TTE (36% sensitive) in the detection of vegetations due to acoustic shadowing of prosthetic valves, especially in the mitral and aortic positions. **TEE should be performed if PVE or pacemaker endocarditis is suspected but is not evident on TTE**.

3. Fungal endocarditis tends to cause larger vegetations than bacterial infections, whereas in Q fever vegetations are often absent. Care should be taken to differentiate bacterial vegetations from myxomas, papillary fibroelastomas, rheumatoid nodules, inflammation involving degenerative valvular lesions, Lambl's excrescences, and nonbacterial endocarditis. **It is essential to interpret images in conjunction with clinical data**.

4. One meta-analysis showed that the **risk of embolization in patients with large vegetations (> 10 mm) was nearly three times higher than in patients with no detectable vegetations** or small vegetations. Prolapsing vegetations and involvement of extravalvular structures increase the overall risk of heart failure, embolization, and need for valve replacement. Vegetations that increase in size, despite appropriate therapy, are also more likely to be associated with adverse events requiring surgery.

5. TEE is indicated in patients with suspected pacemaker or defibrillator endocarditis. The sensitivity of TTE for detecting valvular or lead vegetations is 30%, compared with 90% with TEE.

B. Cardiac catheterization. Left heart catheterization with selective coronary angiography is indicated prior to surgical intervention if there is a suspicion of obstructive coronary disease. The abnormal rocking motion of a dehisced prosthetic valve may be noted on fluoroscopy. Care should be taken to avoid unnecessary coronary angiography or cardiac catheterization in aortic valve endocarditis because of the risk of embolization of vegetations.

C. Central nervous system (CNS) imaging. Computerized tomography (CT), magnetic resonance imaging (MRI), or cerebral angiography should be considered in any patient who has sustained a CNS complication, such as an embolic infarct, intracranial bleed, or mycotic aneurysm, or in the patient with persistent headaches.

D. Body imaging. CT or MRI may be useful in the detection of metastatic infection. The value of CT may increase in the future as spatial resolution improves. **MRI** does not currently have a significant role in assessing cardiac manifestations of IE, owing to intrinsic problems related to temporal resolution.

VII. DUKE CRITERIA. Given the complexity of IE, the diagnosis requires a high index of suspicion. The Duke schema is currently the most sensitive and specific diagnostic set of criteria available. It is particularly useful in diagnosing endocarditis in patients with *S. aureus* bacteremia, those with right-sided endocarditis, and those with negative blood culture results. However, these criteria have not been validated in PVE.

A. The criteria are divided into **definite** (pathologic or clinical), **possible**, and **rejected** diagnostic groups.

B. For a **definite pathologic diagnosis**, either (A or B) of the pathologic findings listed in Table 19.2A is sufficient.

C. For a **definite clinical diagnosis** (Table 19.2B), two major criteria, or one major and three minor, or five minor criteria are needed.

TABLE 19.2A Duke Criteria: Definite Pathologic Diagnosis

A. Microorganisms, as demonstrated by culture or histology in vegetation

Vegetation that has embolized

Intracardiac abscess

B. Pathologic lesions

Vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis

Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation.* 2005;111:394–434.

TABLE 19.2B Duke Criteria: Definite Clinical Diagnosis

Major clinical criteria

1. Positive blood culture results for infective endocarditis
   A. Typical microorganisms (in two or more cultures)
      - Viridans *Streptococcus*
      - *S. bovis*
      - HACEK group
      - *S. aureus*
      - Community-acquired enterococci, in the absence of a primary focus

   B. Persistently positive blood culture
      - Recovery of a microorganism consistent with IE from two blood cultures drawn more than 12 h apart

      or

      - Recovery of a microorganism consistent with IE from all of three or a majority of four or more separate blood cultures, with the first and last draw at least 1 h apart

      or

      - Single positive blood culture for *Coxiella burnetii* or anti–phase 1 IgG antibody titer > 1:800

2. Evidence of endocardial involvement
   A. Positive echocardiogram
      - Oscillating intracardiac mass on valve or supporting structures or in the path of regurgitant jets or on implanted material, in the absence of an alternative anatomic explanation

      or

      - Abscess

      or

      - New partial dehiscence of prosthetic valve

or

   B. New valvular regurgitation (increase or change in preexisting murmur not sufficient)

TABLE 19.2B Duke Criteria: Definite Clinical Diagnosis (*Continued*)

Minor clinical criteria

1. Predisposition:
   - Predisposing heart condition
   - Injection drug use
2. Fever > 38.0° C (100.4° F)
3. Vascular phenomena
   - Major arterial emboli
   - Septic pulmonary infarcts
   - Mycotic aneurysm
   - Intracranial hemorrhage
   - Conjunctival hemorrhages
   - Janeway lesions
4. Immunologic phenomena
   - Glomerulonephritis
   - Osler's nodes
   - Roth's spots
   - Rheumatoid factor
5. Microbiologic evidence
   - Positive blood culture but not meeting major criteria as noted above
   - Serologic evidence of active infection with organism consistent with infective endocarditis

HACEK, *Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella;* IE, infective endocarditis.

Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation.* 2005;111:394–434.

D. The **possible diagnostic** group has findings consistent with IE, including one major criteria and one minor criteria or three minor criteria.

E. For a **rejected diagnosis**, there is a firm alternative diagnosis for clinical manifestations or resolution of clinical manifestations, with antibiotics for 4 days or less, or no pathologic evidence of IE at surgery or autopsy, after antibiotic therapy for 4 days or less.

VIII. THERAPY. Due to the complexity of IE, a team approach (cardiologist, cardiothoracic surgeon, infectious diseases specialist, and pathologist) in the diagnosis and management of this disease cannot be overemphasized. Effective therapy requires identification of the microbial cause, determination of a bactericidal regimen of proven efficacy, an understanding of the intracardiac pathology of IE and its implications for surgery, and effective management of extracardiac complications.

A. Medical therapy

1. **Principles of therapy.** Antibiotic regimens should be bactericidal and chosen in consultation with an infectious diseases specialist. **Measures of antibiotic effectiveness** include the minimum inhibitory concentration (MIC) of antibiotic required to inhibit growth, the minimum bactericidal concentration (MBC) of an antibiotic required to kill an organism, and the serum bactericidal titer (SBT), which is the highest dilution of a patient's serum that kills 99.9% of an inoculum. The SBT is especially helpful when treating unusual organisms, when using unusual antibiotic regimens, or when treatment is failing. The MIC and MBC are not routinely measured, but currently recommended antimicrobial regimens for specific organisms are based on these values.
   a. Combination therapy using a β-lactam agent such as penicillin with an aminoglycoside has a synergistic bactericidal effect in streptococcal IE and is also somewhat effective in a subset of patients with staphylococcal IE. However, aminoglycoside resistance represents the most common and grave obstacle to optimal therapy for enterococcal endocarditis.
   b. A multidrug regimen is recommended for optimal management of staphylococcal PVE. Rifampin has a unique ability to kill staphylococci. However, staphylococci have a relatively high intrinsic mutation rate for the gene controlling the site of rifampin action. Therefore, when large populations of staphylococci are exposed to rifampin, selection of rifampin-resistant organisms is common. Often, antistaphylococcal agent(s) may be administered for 3 to 5 days to reduce the total number of staphylococci before the commencement of rifampin. A multidrug approach (two antibiotics that are known to be active against the staphylococcal isolate in addition to rifampin) may reduce the probability of developing rifampin-resistant subpopulations.
   c. Renal function is an important consideration when using **aminoglycosides or vancomycin**. These antibiotics should be dosed according to estimated creatinine clearance. The following doses outlined are for normal renal function. A vancomycin dose should not exceed 2 g per 24 hours unless serum levels are monitored.
   d. Anticoagulation does not prevent embolization related to IE. In fact, **simultaneous treatment with penicillin and heparin increases the risk** of fatal intracerebral hemorrhage. Warfarin may be given safely during the treatment of patients with PVE.
2. Empiric therapy for IE is often started and continued until the etiologic organism is identified and the antibiotic sensitivities are known, especially in cases with hemodynamic compromise. Occasionally, empiric therapy is administered as a therapeutic trial to help confirm a diagnosis. Empiric therapy should cover the most likely pathogens, including staphylococci (both methicillin-sensitive and methicillin-resistant strains), streptococci, and enterococci. Vancomycin plus gentamicin is the recommended empiric regimen in native valve endocarditis, with the addition of rifampin in PVE. Once an etiologic agent is identified, therapy should be narrowed (see Tables 19.3A–F). Unless clinical or epidemiologic clues suggest an etiologic factor, treatment for culture-negative IE is the same.
3. It is important to point out that when initiating therapy for coagulase-negative staphylococcal PVE, the organism should be assumed to be methicillin-resistant until the laboratory definitively excludes this.
4. Antibiotic therapy **after surgery** is discussed in **VIII.B**.
5. Medical therapies for **specific organisms** are summarized in Tables 19.3A–F.
6. **Uncommon causes of IE.** *C. burnetii* IE is treated with doxycycline and rifampin, trimethoprim–sulfamethoxazole, or fluoroquinolones for at least 3 years and requires surgical intervention in cases of prosthetic valve involvement, CHF, or

TABLE 19.3A Therapies for Native Valve Infective Endocarditis due to Penicillin-Susceptible Viridans *Streptococcus* or *S. bovis*

Medication	Dosage	Duration of therapy (wk)
Penicillin G	12–18 million U per 24 h continuously IV or in 4–6 divided doses	4
or		
Ceftriaxone	2 g once daily IV or IM	4
or		
Penicillin G	12–18 million U per 24 h continuously IV or in 6 divided doses	2[a]
or		
Ceftriaxone *plus*	2 g once daily IV or IM	2
Gentamicin *or* if penicillin allergic	3 mg/kg once daily IV or IM	2
Vancomycin	30 mg per 24 h in 2 divided doses	4

IM, intramuscular; IV, intravenous.

[a]For relatively resistant viridans *Streptococcus* or *S. bovis*, or known cardiac or extracardiac abscess, or for those with creatinine clearance < 20 mL/min, penicillin G dosing is extended to 4 weeks.

Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation*. 2005;111:394–434.

TABLE 19.3B Standard Therapies for Susceptible Enterococci, for Resistant and Nutritionally Variant Viridans *Streptococcus* Infective Endocarditis, and for Prosthetic Valve Endocarditis due to Viridans *Streptococcus* or *S. bovis*

Medication	Dosage	Duration of therapy (wk)
Penicillin G	24 million U per 24 h continuously IV or in 4–6 divided doses	6
or		
Ceftriaxone	2 g once daily IV or IM	6
with or without		
Gentamicin	3 mg/kg once daily IV or IM	2–6[a]
or		
if penicillin allergic, vancomycin	30 mg/kg IV per 24 h in 2 divided doses	6

IM, intramuscular; IV, intravenous.

[a]If penicillin-susceptible strain (minimum inhibitory concentration ≤ 0.12 μg/mL), duration of gentamicin in combination with ceftriaxone is 2 weeks; if penicillin relatively resistant or fully resistant strain (minimum inhibitory concentration > 0.12 μg/mL), duration of gentamicin is extended to 6 weeks.

Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation*. 2005;111:394–434.

TABLE 19.3C Therapies for Infective Endocarditis due to Methicillin-Sensitive *Staphylococcus* in the Absence of Prosthetic Material

Medication	Dosage	Duration of therapy
Nafcillin or oxacillin	2 g IV every 4 h	6 wk
plus		
optional gentamicin	1 mg/kg IV or IM every 8 h	3–5 d
or		
Cefazolin	2 g IV every 8 h	6 wk
plus		
optional gentamicin	1 mg/kg IV or IM every 8 h	3–5 d
or		
if penicillin allergic,		
vancomycin[a]	30 mg/kg per 24 h in 2 divided doses	6 wk

IM, intramuscular; IV, intravenous.

[a]Recommended for methicillin-resistant *Staphylococcus.*

Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation.* 2005;111:394–434.

TABLE 19.3D Therapy for Infective Endocarditis due to Methicillin-Sensitive *Staphylococcus* in the Presence of Prosthetic Material

Medication	Dosage	Duration of therapy (wk)
Nafcillin[a] or oxacillin	2 g IV every 4 h	> 6
plus rifampin	300 mg orally every 8 h	> 6
plus gentamicin	1 mg/kg IV or IM every 8 h	2

IM, intramuscular; IV, intravenous.

[a]For methicillin-resistant *Staphylococcus* or for the penicillin-allergic patient, vancomycin, 30 mg/kg per 24 h IV in two divided doses, is substituted for nafcillin.

refractory infection. *Brucella* IE usually requires surgical intervention in combination with doxycycline and either streptomycin or gentamicin for 8 weeks to 10 months after surgery. *Pseudomonas* IE should be treated with high doses of piperacillin and tobramycin and requires surgical intervention in cases of left-sided infection.

7. **Fungal IE.** When fungal IE is diagnosed, the standard of care involves a **combined medical/surgical approach**.
   a. The mainstay of antifungal drug therapy is **amphotericin B** with or without **flucytosine** (a synergistic effect).

TABLE 19.3E Therapy for Infective Endocarditis due to HACEK (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, and Kingella)* Microorganisms

Medication	Dosage	Duration of therapy
Ceftriaxone[a]	2 g once daily IV or IM	4
or		
Ampicillin–sulbactam[a]	3 g IV every 6 h	4
or		
Ciprofloxacin	1,000 mg orally once daily *or* 400 mg IV every 12 h	4

IM, intramuscular; IV, intravenous.
[a]The third-generation cephalosporins or ampicillin–sulbactam therapy should be considered the drugs of choice. Length of therapy for prosthetic valve infective endocarditis should be 6 weeks. A fluoroquinolone should be considered as an alternative agent for patients unable to tolerate β-lactam therapy.
Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis: diagnosis, antimicrobial therapy, and management of complications. *Circulation.* 2005;111:394–434.

TABLE 19.3F Therapy for *Pseudomonas aeruginosa* and Other Gram-Negative Bacilli (Enterobacteriaceae)[a]

Extended-spectrum penicillin (ticarcillin or piperacillin)
or
third-generation cephalosporin
or
imipenem
plus aminoglycoside

[a]Combination therapy is recommended. The final choice of antibiotic therapy is to be made after sensitivity results are available.

(1) Amphotericin B is infused in 5% dextrose over 2 to 4 hours at a dose of 0.7 to 1.0 mg/kg daily. Larger doses (1 to 1.5 mg/kg daily) are recommended for the management of PVE caused by *Aspergillus* spp.
(2) The major toxicity of amphotericin B is **renal dysfunction**. Liposomal preparations may be less nephrotoxic.
(3) The primary toxicity of flucytosine is **bone marrow suppression**; for this reason, flucytosine blood levels may be useful during therapy.

b. After 1 to 2 weeks of full-dose amphotericin B therapy, surgery should be performed because effective penetration of the medicine into vegetations is unlikely. Valve replacement becomes necessary in almost all cases of fungal IE.

c. Long-term oral suppressive therapy with antifungal agents such as fluconazole or itraconazole is commonly recommended to prevent relapse.

B. Surgical therapy (Table 19.4). Surgery is indicated in approximately 25% to 30% of cases during the acute phase of infection and in another 20% to 40% in subsequent or secondary phases. Antibiotic therapy combined with valve replacement and cardiac reconstruction results in higher survival rates and fewer relapses or rehospitalizations and lower late endocarditis–related mortality than do antibiotics alone in patients with complicated IE.

1. The **fundamental principles** of operative procedures for IE involve debridement of infected tissue, removal of all nonviable tissue, reconstruction of the involved area, and restoration of valve competence. There is general consensus for surgical intervention in any of the following situations: refractory CHF due to significant valve dysfunction, native and PVE caused by *S. aureus*, uncontrolled infection, failed antimicrobial therapy with perivalvular extension of infection, most cases of PVE, most cases of fungal IE, and established abscess. Controversial indications include the presence of more than one serious systemic embolic event or one embolus with a large residual vegetation. These indications are not absolute and must be implemented with a careful risk–benefit analysis (see the American College of Cardiology/American Heart Association [ACC/AHA] guidelines for surgical intervention in Table 19.4).
2. CHF (New York Heart Association class III or IV) is the strongest indication for surgery in IE, as 90% of all deaths result from CHF. It should be noted

TABLE 19.4 ACC/AHA Guidelines: Surgical Intervention for Infective Endocarditis

Class I

1. Acute native valve IE presenting with valve stenosis or regurgitation that results in heart failure
2. Acute native valve IE presenting with AR or MR with hemodynamic evidence of elevated LVEDP or LAP
3. Native valve IE caused by fungal or other highly resistant organisms
4. Native valve IE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions
5. Prosthetic valve IE presenting with heart failure
6. Prosthetic valve IE presenting with dehiscence confirmed by fluoroscopy or echocardiography
7. Prosthetic valve IE presenting with increasing obstruction or worsening regurgitation
8. Prosthetic valve IE presenting with complications such as abscess formation

Class IIa

1. Native valve IE presenting with mobile vegetations > 10 mm with or without emboli
2. Prosthetic valve IE presenting with persistent bacteremia or recurrent emboli despite appropriate antibiotic therapy
3. Prosthetic valve IE presenting with relapsing infection

IE, infective endocarditis; AR, aortic regurgitation; MR, mitral regurgitation; LVEDP, left ventricular end-diastolic pressure; LAP, left atrial pressure

Adapted from the ACC/AHA 2006 Guidelines for the Management of Patients with Valvular Heart Disease. JACC 2006.

that the benefit of surgery persists even in the presence of comorbidities, such as acute renal failure, and surgery should not be delayed in the setting of life-threatening heart failure or cardiogenic shock if the patient is likely to recover after surgery.

3. PVE usually requires a combined medical/surgical approach.
4. **Patients with CNS infarcts or bleeds.** Special attention must be paid to the presurgical candidate who may have had a CNS infarct or bleed, since large doses of heparin are required for cardiopulmonary bypass. Several studies report a significant risk of postoperative neurologic deterioration or even death in patients with recent CNS complications of IE. The best management in the scenario of hemodynamic instability and new-onset embolic stroke has not been addressed in randomized clinical studies. When possible, cardiac surgery is delayed for at least 4 days, ideally 10 days postinfarction in those with a CNS embolic infarct, and for 21 days following an intracranial hemorrhage. However, some patients may need early surgery despite a recent stroke if they are at high risk for recurrent emboli. **If a mycotic aneurysm is found, the timing of surgery should be reconsidered, and any prosthesis that requires postoperative anticoagulation should be avoided.** A ruptured mycotic aneurysm should be resected, clipped, or embolized **before** cardiac operation.
5. Metastatic infection, usually attributed to *S. aureus*, should be drained if accessible.
6. The optimal duration of **antibiotic therapy after surgery** for IE is not known.
   a. For **native valve IE** caused by an antibiotic-resistant organism with subsequent negative cultures, preoperative plus postoperative antibiotic therapy should consist of a full course of recommended treatment.
   b. For patients with **positive intraoperative cultures**, a full course of therapy should be given postoperatively.
   c. Patients with prosthetic valves who are undergoing surgery for IE should receive a full course of antibiotics postoperatively when organisms are discovered in resected material.

C. The optimal management of **pacer or defibrillator endocarditis** has been controversial in the literature, especially regarding the necessity for device removal.

1. The success rate without removal of the entire device is low because typically the entire device is infected. Most studies suggest that the complete explantation of all hardware combined with antibiotic therapy is the optimal management.
2. The optimal route or duration of antibiotics remains unclear in the literature. Experience suggests that a prolonged course of intravenous antibiotics is needed.
3. The timing of device reimplantation is another important issue. It is prudent to provide sufficient duration of antibiotic therapy to eradicate bacteremia and to suppress or eradicate endocardial infection prior to reimplantation in order to minimize the risk of reinfection of the new device. Studies have shown that reimplantation is successfully performed at a median of 7 days (5 to 25 days) after explantation.

IX. COMPLICATIONS

A. Table 19.5 lists the complications of IE.

B. Valve ring abscess is a noteworthy complication of PVE, seen with mechanical and bioprosthetic valves and also occasionally seen in severe infection of native valves. Infection of the sutures used to secure the sewing ring to the periannular tissue may result in dehiscence of the valve. The clinical finding of a new perivalvular leak in a patient with PVE is worrisome. Risk factors for abscess formation include persistent fever, CHF, a history of intravenous drug use, infection with a virulent organism, and PVE.

TABLE 19.5 Complications

Cardiac complications
Congestive heart failure (leading cause of death)
Abscess (pericardial, aortic annular, or myocardial)
Conduction abnormalities (due to invasive disease)
Coronary embolism
Mycotic aneurysm (often clinically silent)
Valvular regurgitation (cusp/leaflet flail or perforation)
Valvular stenosis
Prosthetic dehiscence
Septal perforation (ventricular septal defect)
Extracardiac complications
Systemic embolism (stroke, renal infarct, splenic infarct, or ischemic limb)
Mycotic aneurysm
Abscess
Immune complex deposition (glomerulonephritis)

X. RESPONSE TO THERAPY. Although a reduction in the size of vegetations during antimicrobial therapy suggests therapeutic success, vegetations may persist unchanged despite microbiologic cure. Significant enlargement of a vegetation during treatment indicates possible treatment failure and constitutes a relative indication for surgery.

- **A.** Blood cultures should be obtained during therapy for IE to ensure eradication of the organism (see Section **V.A.3**).
- **B.** Defervescence usually follows 3 to 7 days of successful antimicrobial therapy. **Persistent or recurrent fever may represent therapeutic failure, drug fever, a secondary nosocomial infection, or intracardiac or extracardiac abscess formation**. Generally, if fever persists for more than 7 days or if blood cultures are positive beyond the first week of antibiotic therapy, the treatment is considered a failure.
- **C.** Relapses, should they occur, usually manifest clinically within 4 weeks and can be confirmed by blood cultures. With a combined medical and surgical approach, recurrent PVE occurs in 6% to 15% of patients.
- **D.** **The frequency of emboli falls rapidly after 1 to 2 weeks of antibiotic therapy,** and the risk is considered to be greatest in the setting of large vegetations (> 10 mm in diameter) and specific infections (*S. aureus* and *Candida*).
- **E.** Medical management is successful in many patients with IE; however, surgery is required in approximately 25% to 33% of cases.

XI. PROGNOSIS. The prognosis depends on **the virulence of the causative organism, the underlying health of the patient, the valvular structures, the duration of the infection, and the presence or absence of CHF**. The overall mortality of IE is around 20% to 30%. Notably, the mortality rates in early PVE (40% to 80%) are much higher than in late PVE (20% to 40%). Five-year survival rates after surgery for PVE have ranged from 54% to 87%. In *S. aureus* IE, mortality has decreased from 50% to 60% to 15% to 30% in recent years. The presence of the factors listed in Table 19.6 should trigger an early and aggressive management plan.

TABLE 19.6 Factors and Complications That Predispose to a Poor Outcome

Congestive heart failure (leading adverse prognostic factor)
Nonstreptococcal disease
Aortic valve involvement
Infection of a prosthetic valve
Older age
Abscess formation
HIV with CD4 count < 200 cells/mm^3
Delayed diagnosis
CNS or coronary embolization
Recurrent infective endocarditis

CNS, central nervous system; HIV, human immunodeficiency virus.

A. There has been an increasing demand to develop an endocarditis risk score for predicting mortality and surgical outcomes in IE. One barrier to the development of this model is inconsistencies in the prognostic value of individual parameters in the published data. These differences may in part be due to time dependencies of various risk factors. One study evaluated risk factors in a time-dependent manner in order to derive a validated risk score for the prognostic evaluation of IE in patients before and during early hospitalization. Factors that contributed to increased mortality included older age, CHF, lower platelet count, higher creatinine, and severe embolic events, consistent with previous studies. A recent study used the Society of Thoracic Surgery database to develop a surgical mortality risk scoring system. Although several studies have attempted to evaluate the most significant predictors of risk, a standardized risk scoring model has yet to be established.

XII. PROPHYLAXIS. Revised IE prophylaxis guidelines from the AHA concluded that **only those patients at highest risk for adverse outcomes from IE require prophylaxis** prior to certain dental or surgical procedures (Tables 19.7A and 19.7B). This is based on studies suggesting that IE is more likely to occur from everyday activities such as flossing or brushing teeth than from dental procedures, and that an extremely small number of cases of IE might be prevented by antibiotic prophylaxis for dental, gastrointestinal, or genitourinary procedures. It is a standard practice (AHA guidelines) that at-risk individuals be counseled and advised to carry a card with current prophylaxis recommendations. Failure to adhere to this practice may invite litigation. A recent study suggests that an echocardiographic report, stating the endocarditis risk and need for prophylaxis, improves compliance with AHA recommendations.

A. In deciding the need for antibiotic prophylaxis, two factors must be considered: the risk associated with the specific valvular lesion (Table 19.7A) and the type of procedure to be performed (Table 19.7B). Patients for whom antibiotic prophylaxis for IE is recommended include those with **prosthetic heart valves, prior IE, postcardiac transplantation valvulopathy, and certain patients with congenital heart disease** (Table 19.7A). Routine IE prophylaxis is no longer recommended in most cardiac conditions, including mitral valve prolapse, rheumatic heart disease, bicuspid aortic valve, calcific aortic stenosis, atrial septal defect, and ventricular septal defect.

TABLE 19.7A Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Infective Endocarditis

Prophylaxis for endocarditis recommended
Prosthetic heart valves
Previous infective endocarditis
CHD
Unrepaired cyanotic CHD (including palliative shunts or conduits)
Repaired CHD with residual defect at, or adjacent to, the site of repair
During the first 6 mo after repair of congenital heart defects using prosthetic material or device
Cardiac transplantation recipients who develop cardiac valvulopathy

CHD, congenital heart disease.

Adapted from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation.* 2007;115:1–19.

TABLE 19.7B Recommendations for Prophylaxis in Dental or Surgical Procedures

Prophylaxis recommended only in patients at highest risk of adverse outcome from infective endocarditis (Table 19.7A)
Oropharyngeal procedures
Dental procedures that involve manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa
Tonsillectomy and/or adenoidectomy
Respiratory procedures
Invasive procedures involving incision
Miscellaneous
Procedures on infected skin or musculoskeletal tissue

Adapted from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation.* 2007;115:1–19.

B. Endocarditis prophylaxis following **dental or oral procedures** is directed primarily against viridans *Streptococcus*; following **genitourinary and gastrointestinal surgery** it is directed primarily against *Enterococcus* organisms.

C. **Routine antibiotic prophylaxis solely to prevent IE is no longer advised prior to gastrointestinal or genitourinary procedures.** This is based upon an increasing frequency of antimicrobial-resistant strains of enterococci and a lack of evidence conclusively linking these procedures to IE.

D. Available evidence supports a shift in emphasis away from dental procedures and antibiotic prophylaxis toward a greater **emphasis on maintaining good oral hygiene** and improved access to dental care in patients at risk for IE.

TABLE 19.7C Prophylactic Regimens

Clinical situation	Antibiotic	Dose
Standard prophylaxis	Amoxicillin	2 g PO 1 h before procedure
Unable to take oral medications	Ampicillin *or*	2 g IV or IM within 30 min before procedure
	Cefazolin or ceftriaxone	1 g IV or IM within 30 min before procedure
Penicillin allergy	Clindamycin *or*	600 mg PO 1 h before procedure
	Cephalexin *or*	2 g PO 1 h before procedure
	Azithromycin *or* clarithromycin	500 mg 1 h before procedure

IM, intramuscular; IV, intravenous; PO, per oral.

Adapted from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association. *Circulation.* 2007;115:1–19.

E. Prophylaxis against viridans *Streptococcus* is advised in patients at highest risk of IE who undergo **invasive procedures of the respiratory tract** that involve incision or biopsy (i.e., tonsillectomy or adenoidectomy). Routine endocarditis prophylaxis prior to **vaginal delivery** or hysterectomy is not recommended.

F. Incision and drainage or other procedures involving infected tissue may result in bacteremia. For nonoral soft-tissue infections, an antistaphylococcal penicillin or first-generation cephalosporin is an appropriate choice of prophylaxis.

G. Prophylaxis regimens are listed in Table 19.7C. **Cardiac surgical patients** who undergo placement of prosthetic heart valves or other prosthetic material should receive antibiotic prophylaxis, primarily directed against *S. aureus.* A first-generation cephalosporin is commonly used, but the choice of antibiotic should be influenced by the antibiotic susceptibility pattern at each hospital. Prophylaxis should be started immediately before the procedure, repeated during prolonged procedures, and continued for no more than 48 hours. **A careful preoperative dental evaluation** is recommended so that, whenever possible, required dental treatment can be completed before cardiac valve surgery.

H. **Patients after cardiac transplantation** are at moderate risk for endocarditis because of continuous immunosuppression and the tendency for acquired valvular dysfunction (tricuspid regurgitation from endomyocardial biopsy or rejection).

I. Pneumococcal vaccination is recommended for all patients with prosthetic heart valves.

XIII. CONTROVERSIES

A. Therapy

1. Short courses of antibiotics (2 weeks) have shown some efficacy in the injection drug user population, as have oral antibiotics in the same population. However, intravenous antibiotics are indicated until conclusive data concerning attentive regimens are available. At least 5 to 7 days of inpatient therapy is advocated before considering outpatient treatment.

2. Correct timing of surgery is often the most difficult and critical decision in the management of IE. It is important to balance the need for medical stabilization

with timely surgery. Kiefer et al. (1) conducted a large multicenter randomized trial of over 4,000 patients with IE and heart failure and showed that surgical intervention during initial hospitalization was associated with decreased inhospital and 1-year mortality rates. In patients with large mitral or aortic valve vegetations (> 10 mm), early surgery has been found to be associated with decreased mortality and embolic events when compared with conventional medical therapy (3% vs. 23%) in the recently published Early Surgery Versus Conventional Treatment in Infective Endocarditis (EASE) trial. In this trial, patients who had surgery within 48 hours had a decreased rate of all-cause death.

3. Valve repair is a reasonable option for mitral, tricuspid, and, less often, aortic IE in which the infection has been controlled. The choice among mechanical, bioprosthetic, and biologic devices may be made according to the usual criteria. However, in the setting of aortic prosthetic endocarditis, a homograft or an autograft is less likely to become infected than either a xenograft or a mechanical valve and is considered the optimal valve substitute.

ACKNOWLEDGMENTS: *The authors thank Drs. Mateen Akhtar, Xiao-Fang Xu, and Mark Murphy for their contributions to earlier editions of this chapter.*

CHAPTER 20

Chetan Vagesh Hampole

Rheumatic Fever

I. INTRODUCTION. Rheumatic fever (RF) is a systemic autoimmune disorder related to prior streptococcal infection and is the leading cause of heart disease in those under the age of 40 years living in developing nations.

A. The incidence of RF and prevalence of rheumatic heart disease **vary substantially among countries**. In many developing countries, the incidence of acute RF approaches or exceeds 200 per 100,000, whereas in the Unites States, it is estimated to be less than 1 per 100,000. Since the first half of this century, there has been a

gradual decline in the incidence of RF in the United States, Japan, and most European countries. This is due to improved public health and living conditions, the development of modern antibiotics, as well as a shift in the endemic strains of group A streptococcus (GAS). Localized outbreaks of RF have occurred in the United States as recently as the mid-1980s.

B. RF is more common among populations at high risk for streptococcal pharyngitis, such as military recruits, those in close contact with school-aged children, and persons of low socioeconomic status. It most commonly occurs between the ages of 5 and 18 years. RF affects both sexes equally, except for Sydenham's chorea, which is more prevalent in females after puberty.

II. CLINICAL PRESENTATION. The clinical manifestations of RF **develop 3 weeks after a GAS tonsillopharyngitis**. It is important to note that one-third of patients with RF do not remember having had a sore throat. Patients with RF present initially with a sudden onset of constitutional symptoms, including fever (101°C to 104°C), malaise, weight loss, and pallor. An exudative and proliferative inflammatory process involving collagen fibrils characterizes the acute phase of RF. **Multiple organ systems**, such as the dermis, central nervous system, synovium, and heart, may be involved. In addition, manifestations may include serositis and involvement of the lungs, kidneys, and central nervous system.

A. Diagnostic criteria

1. The **Jones criteria** are designed to aid in the diagnosis of the first episode of RF. It can be diagnosed when a **previous upper airway infection with GAS is detected in conjunction either with two major manifestations or with one major and two minor manifestations**. Major manifestations include arthritis, carditis, chorea, erythema marginatum, and subcutaneous nodules. Minor manifestations include fever, arthralgias, high C-reactive protein (CRP) level or high erythrocyte sedimentation rate (ESR), and a prolonged PR interval on electrocardiogram (ECG) (Table 20.1).
2. In some circumstances, the **diagnosis of RF can be made without strict adherence to Jones criteria**, as in cases of indolent or recurrent carditis or isolated cases of chorea when other causes have been excluded.

B. Major manifestations (Table 20.1)

1. **Carditis.** This is the most serious and is often regarded as the most specific manifestation of RF, affecting 41% to 83% of patients. It may manifest

TABLE 20.1 Diagnosis of Rheumatic Fever[a]

GAS infection	Major Jones criteria	Minor Jones criteria
Culture	Carditis	Fever
ASO titers	Arthritis	Arthralgia
Anti-DNase B	Sydenham's chorea	High ESR or CRP
Other antistreptococcal antibodies	Subcutaneous nodules	Prolonged PR
Streptococcal antigens	Erythema marginatum	

ASO, antistreptolysin *O*; anti-DNase, antideoxyribonuclease B; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A streptococcus.

[a]The diagnosis of rheumatic fever requires confirmation of a previous ***GAS infection*** with at least one of the methods listed above together with either ***two major criteria or one major criterion and two minor criteria***.

as pancarditis affecting the endocardium, myocardium, and pericardium simultaneously.

- **a.** Cardiac involvement ranges from an asymptomatic presentation to progressive congestive heart failure and death.
- **b.** The most typical manifestations include **increased heart rate, rhythm disturbances, new murmurs or pericardial friction rub, cardiomegaly, and heart failure**.
- **c.** Heart failure is rare in the acute phase; if present, it is usually the result of myocarditis.
- **d.** The most characteristic component of rheumatic carditis is a valvulitis (endocarditis) involving the mitral and aortic valves.
  - **(1)** Mitral insufficiency is the hallmark of rheumatic carditis. Aortic insufficiency is less common and is almost always associated with mitral insufficiency. As a rule of thumb, patients under the age of 30 years tend to present with isolated mitral regurgitation, whereas patients develop mitral stenosis during the third decade, with mixed mitral valve disease predominating thereafter.
  - **(2)** Acute mitral valve regurgitation produces an apical systolic murmur that may be accompanied by a mid-diastolic Carey Coombs murmur of relative mitral stenosis (a high-pitched early diastolic murmur that varies from day to day). Right-sided valves are rarely involved.
  - **(3)** Those valvular lesions that are diagnosed by echocardiogram but are clinically silent usually heal without scarring and have a good prognosis. Controversy exists whether echocardiographic findings of mitral regurgitation or aortic insufficiency constitute subclinical rheumatic carditis sufficient to meet the Jones criteria.
- **e.** Pericarditis may cause chest pain, friction rubs, and distant heart sounds but is often clinically silent.

2. **Arthritis.** This is the **most common manifestation of RF but is the least specific**. It occurs in 80% of patients and is described as **painful, asymmetric, migratory, and transient. It involves large joints**, such as the knees, ankles, elbows, wrists, and shoulders. It is **more common in older patients and improves markedly with the use of salicylates** within 48 hours of treatment. Monoarthritis, oligoarthritis, and involvement of small joints of the extremities are less common. However, arthritis of the first metatarsophalangeal joint, enthesopathy, and axial involvement, especially of the cervical spine, have also been reported. **Arthritis of RF is benign and self-limiting** (lasting 2 to 3 weeks) and does not result in permanent sequelae. Inflammatory changes without signs of infection are seen in the joint fluid.
3. **Sydenham's chorea.** Also known as Saint Vitus' dance or chorea minor, this **extrapyramidal disorder is characterized by purposeless and involuntary movements** of face and limbs, muscular hypotonia, and emotional lability.
   - **a.** Initial manifestations include difficulty in writing, talking, or walking. Handwriting may deteriorate; speech may change to an explosive and halting tone; and the patient may become uncoordinated and easily frustrated.
   - **b.** Symptoms tend to be more evident when the patient is under stress or awake and usually disappear during sleep.
   - **c.** Sydenham's chorea is a **delayed manifestation of RF**, usually appearing 3 months or more after an upper airway infection; it is often the sole manifestation of acute RF. Chorea has been reported in up to 30% of the patients. Most cases tend to follow a benign course, with complete resolution of symptoms in 2 to 3 months, although cases in which symptoms persisted for > 2 years have been reported.

d. It is important to **differentiate the symptoms of Sydenham's chorea from tics, athetosis, conversion reactions, hyperkinesia, and behavioral abnormalities**.

4. **Subcutaneous nodules.** These usually measure 0.5 to 2 cm and are **firm, painless, and freely mobile nodules that can be isolated or found in clusters** over the **extensor surfaces** of joints (knees, elbows, and wrists), bony prominences, tendons, dorsum of foot, occipital region, and cervical processes. They are seen in up to 20% of patients with RF and last for a few days. The skin overlying the nodules is freely mobile and shows no signs of discoloration or inflammation.
5. **Erythema marginatum.** This is an **evanescent erythematous macular rash** with a pale center of irregular shape. It is **usually nonpruritic and tends to disappear after a few days**. It is highly specific, occurring in < 5% of patients, and is obvious only in fair-skinned individuals. The lesions vary in size and affect mainly the trunk, abdomen, and inner aspect of arms and thighs, but not the face. The rash may be induced by application of heat. Its presence is **suggestive of coexisting carditis**.

C. **Minor manifestations.** Fever and arthralgias are common, but nonspecific findings of RF that can be used to support the diagnosis of RF when only a single major manifestation is present (Table 20.1).

1. Fever is encountered during the acute phase of the disease and does not follow a specific pattern.
2. Arthralgia is defined as pain in one or more large joints without objective findings of inflammation on physical examination.
3. Other clinical manifestations of RF include **abdominal pain, epistaxis, acute glomerulonephritis, rheumatic pneumonitis, hematuria, and encephalitis**. These are not included as diagnostic criteria for the diagnosis of RF.

III. ETIOLOGY AND PATHOPHYSIOLOGY

A. The association between tonsillopharyngitis–scarlet fever epidemics and acute RF in the 1930s, the findings of high levels of antistreptolysin *O* (ASO) in sera of patients with RF, and the confirmation of antibiotics as an efficient mode of prophylaxis of RF provide **strong evidence that GAS is the agent causing initial and recurrent attacks of RF**.

1. Acute RF might not be caused directly by the bacteria but rather through an immunologic mechanism. Specifically, it appears that patients who develop RF demonstrate a hyperimmune response to GAS, and the level of the immune response correlates with the severity of the RF manifestations. Supporting evidence includes onset approximately 3 weeks following an upper respiratory tract infection, rarity before the age of 5 years when the immune system is still immature, and cross-reactivity between streptococcal cellular antigens and proteins present in human connective tissue.
   a. The most important antigenic structures (M, T, and R proteins) are localized in the external layer of the bacterial cell wall.
   b. The M protein not only is responsible for type-specific immunity but also has a powerful antiphagocytic action and is classically regarded as a marker of streptococcal rheumatogenic potential. Patients with acute RF possess high levels of antibodies targeted against this protein. Specific M serotypes of GAS have long been recognized as strong stimulators of a robust immune response and are associated with an increased risk of developing RF. Those M serotypes associated with impetigo or pyoderma may cause glomerulonephritis but are not associated with RF.
2. In epidemics of streptococcal pharyngitis, it is estimated that approximately **3% of untreated individuals will go on to develop RF**. However, recurrence of

RF is seen in about 50% of patients with a history of RF. For endemic GAS pharyngeal infections, the incidence of RF is much less common.

B. Numerous epidemiologic studies favor a **familial and even genetic predisposition**. A monoclonal antibody to B-cell alloantigen (D8/17) is almost universally detected in patients with RF, whereas this antibody is present in < 14% of the general population. In addition, susceptibility to RF has also been linked with D-related human leukocyte antigen 1, 2, 3, and 4 haplotypes. These genetic markers may be useful in the future to identify individuals susceptible to acute RF.

IV. LABORATORY EXAMINATION AND DIAGNOSTIC TESTING. RF is a clinical diagnosis because there is no single laboratory study that is diagnostic of RF.

A. Supporting evidence of antecedent GAS infection can be obtained through cultures, antigen test, or serum antistreptococcal antibody test.

1. Although no consensus exists regarding which tests to order at what time, commonly ASO titers and cultures are initially obtained when RF is suspected. Other tests as detailed in the subsequent text are useful only under certain conditions.
2. A negative throat culture is usually sufficient to withhold antibiotic treatment in most cases, especially if clinical suspicion of RF is low.
3. Elevated or rising ASO titers provide solid evidence for recent GAS infection. **A greater than twofold rise in ASO titers compared with convalescent titers is diagnostic**.
4. The probability of detecting a previous GAS infection can be increased by obtaining repeated ASO tests or by looking for antibodies to other streptococcal antigens, such as **antideoxyribonuclease B**.
5. A slide agglutination test is commercially available, which measures antibodies to several streptococcal antigens. Although this test is simple to perform, it is **not well standardized and is not very reproducible**. Therefore, it is **not recommended** as a definitive test for prior GAS infection.

B. Biopsies

1. Aschoff's nodules, a form of granulomatous inflammation, can be seen in the proliferative stage and are considered pathognomonic for rheumatic carditis. They are encountered in 30% to 40% of biopsies from patients with primary or recurrent episodes of RF. Such nodules are most often found in the interventricular septum, the wall of the left ventricle, or the left atrial appendage.
2. The histologic findings of endocarditis include edema and cellular infiltration of valvular tissue. Hyaline degeneration of the affected valve results in the formation of verrucae at its edge, preventing the normal leaflet coaptation. If the inflammatory process persists, fibrosis and calcification develop, leading to valvular stenosis.
3. Endomyocardial biopsy does not help in diagnosing first attacks of rheumatic carditis. It is **useful in distinguishing chronic inactive rheumatic heart disease from acute rheumatic carditis**. As such, it is rarely indicated except in cases where recurrent carditis is suspected but cannot be confirmed otherwise.

C. Other blood tests

1. As in any inflammatory process, **leukocytosis, thrombocytosis, or hypochromic or normochromic anemia** may be noted.
2. The favored tests to measure acute phase response are ESR and CRP. Although these tests are nonspecific, they may be helpful in monitoring the inflammatory activity of the disease. These levels are **almost always elevated during the acute phase of RF in patients with arthritis and polyarthritis and are usually normal in patients with chorea**.

D. Radiography. Chest radiography may identify increased cardiac size, increased pulmonary vasculature, or pulmonary edema.

E. Electrocardiography and echocardiography. In patients in whom **carditis is subtle and signs of valvular involvement may be mild or transient, a baseline echocardiogram and ECG** may help provide evidence of carditis.

1. The most common finding in the **ECG** is the presence of **PR prolongation and sinus tachycardia**. Myocarditis may prolong the QT interval. In cases of pericarditis, low-voltage QRS complexes and ST-segment changes in the precordial leads can be observed.
2. Echocardiography is likely to show mitral regurgitation or aortic insufficiency. Calcifications of the leaflets and subvalvular apparatus are present in the chronic, not acute, phase of rheumatic heart disease.

V. THERAPY.

It is generally recommended that **patients with suspected RF be admitted for close observation and workup**.

A. Carditis

1. Secondary prophylaxis with penicillin has been shown to reduce not only streptococcal infections but recurrent attacks of acute RF as well. Patients with mild carditis should receive secondary prophylaxis for 10 years after the most recent attack or at least until the age of 25 years, whichever is longer. More severe valvular damage necessitates lifelong secondary prophylaxis.
2. Congestive heart failure should be managed with standard therapy (Chapters 8 and 9).
3. In patients with significant cardiac involvement, corticosteroids are preferred over salicylates. The recommended dose of corticosteroid is 1 to 2 mg/kg/d (maximum of 60 mg/d). Salicylate or steroid therapy does not affect the course of the disease; therefore, the duration of anti-inflammatory therapy is somewhat arbitrary and is guided by the severity of disease and the response to therapy. Commonly, therapy is needed for 1 month in patients with relatively mild cardiac involvement. Therapy should be continued until there is sufficient clinical and laboratory evidence of disease inactivity.
4. After cessation of anti-inflammatory agents, relapse with mild symptoms may occur. **A gradual reduction in steroid dosing is necessary to avoid relapses**. If **symptoms are mild, they usually subside without specific treatment**. For **severe symptoms, treatment with salicylates** should be tried before restarting corticosteroids. Administering salicylate therapy (75 mg/kg/d) while tapering corticosteroids may reduce the likelihood of a relapse.
5. Corticosteroids, despite relieving symptoms or carditis, do not prevent valvular damage.

VI. PREVENTION.

See Table 20.2.

A. Primary prevention. The most important step in the management of RF is the eradication of GAS infection, which prevents chronic and repetitive exposure of antigenic streptococcal components to the host immune system. However, **no treatment can eradicate GAS completely in all patients because of high colonization rates**.

1. Early therapy is advisable because it reduces both morbidity and the period of infectivity. Studies have shown that antimicrobial therapy, even when started 9 days after the onset of acute streptococcal pharyngitis, is still effective in preventing primary attacks of RF.
2. Penicillin is the agent of choice primarily for its narrow spectrum of activity, long-standing proven efficacy, and low cost.
   a. Best results are achieved with a **single intramuscular dose of penicillin G benzathine**. An intramuscular regimen is preferred in patients unlikely to complete a 10-day course of oral therapy or in patients with personal or

TABLE 20.2 Prevention of Rheumatic Fever

Drug	Dosage	Route	Duration
Primary prevention			
Benzathine (penicillin G)	600,000 U (≤ 27 kg) 1.2 million U (≥ 27 kg)	IM	Once
	or		
Penicillin V (children)	250 mg (2–3 times/d)	Oral	10 d
Penicillin V (adolescents and adults)	500 mg (2–3 times/d)	Oral	10 d
Penicillin-allergic patients			
Erythromycin ethyl succinate	40 mg/kg/d (2–4 times/d up to 1 g/d)	Oral	10 d
Erythromycin estolate	20–40 mg/kg/d (2–4 times/d up to 1 g/d)	Oral	10 d
Secondary prevention			
Benzathine (penicillin G)	1.2 million U	IM	q3-4wk
or			
Penicillin V	250 mg	Oral	bid
or			
Sulfadiazine	0.5 g (≤ 27 kg) 1.0 g (> 27 kg)	Oral	qd
Penicillin- and sulfadiazine-allergic patients			
Erythromycin	250 mg	Oral	bid

bid, twice a day; IM, intramuscular; qd, every day.
Adapted from Dajani AS. Rheumatic fever. In: Braunwald E, ed. *Heart Disease*: *A Textbook of Cardiovascular Medicine*. 5th ed. Philadelphia, PA: WB Saunders; 1997:1769–1775.

family history of RF or rheumatic heart disease. This preparation is painful; **preparations that contain procaine penicillin are less painful**.

b. In comparison with the intramuscular regimen, the oral regimen has several disadvantages, such as lower compliance due to its longer duration, more complicated dosing schedules, drug interactions, and, more importantly, socioeconomic factors. The oral antibiotic of choice is penicillin V (phenoxymethylpenicillin) (see Table 20.2 for dosage information). A broader spectrum penicillin, such as amoxicillin, offers no microbiologic advantage over penicillin.

3. Patients allergic to penicillin:
   a. Oral erythromycin can be used. The recommended dosage is erythromycin estolate or erythromycin ethyl succinate for 10 days. The maximum dose of erythromycin is 1 g/d.
   b. Although uncommon in the United States, **strains resistant to erythromycin** have been found in some areas of the world and have caused treatment failures. The newer **macrolides, such as azithromycin**, have the advantage of a short treatment duration (5 days) and few gastrointestinal side effects. These can be used as second-line therapy for patients 16 years or older with GAS pharyngitis. The recommended dosage is 500 mg as a single dose on the first day followed by 250 mg once daily for 4 days.
   c. Another alternative regimen for penicillin-allergic patients is a **10-day course with an oral cephalosporin**. A first-generation cephalosporin with a narrower spectrum of action (cefadroxil or cephalexin) is preferable to the broader spectrum antibiotics such as cefaclor, cefuroxime, cefixime, and cefpodoxime. Several reports support the evidence that a 10-day course with oral cephalosporin is superior to a 10-day course with oral penicillin and a 5-day course with selected oral cephalosporins is comparable to a 10-day course with oral penicillin for the eradication of GAS.
   d. Sulfa-derived antibiotics **(sulfonamides and trimethoprim) do not eradicate GAS** in patients with pharyngitis, and **tetracycline should be avoided** because of the high prevalence of resistant strains.

B. **Secondary prevention.** Prophylaxis for preventing recurrences should **start as soon as RF or rheumatic heart disease is diagnosed**, as recurrences can sometimes be asymptomatic.
   1. Penicillin in doses of 600,000 IU (patient's weight < 27 kg) to 1.2 million IU (patient's weight > 27 kg) every 4 weeks is the recommended regimen in most circumstances. The interval is reduced to 3 weeks for individuals at high risk for developing acute RF or living in endemic areas.
   2. The duration of prophylaxis depends on the individual situation. Table 20.3 provides additional information.
      a. Prophylaxis for **recurrent RF in patients without cardiac manifestations** should be continued for 5 years after the last RF attack or up to the age of 21 years, whichever is longer.

TABLE 20.3 Duration of Therapy for Secondary Prevention of Rheumatic Fever

Disease state	Duration of therapy
RF + carditis + residual valvular disease	At least 10 y postepisode and at least until the age of 40 y. Lifelong prophylaxis may be required
RF + carditis without valvular disease	10 y or beyond adulthood, whichever is longer
RF without carditis	5 y or until the age of 21 y, whichever is longer

RF, rheumatic fever.

Adapted from Dajani AS. Rheumatic fever. In: Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine*. 5th ed. Philadelphia, PA: WB Saunders; 1997:1769–1775.

b. For **patients with RF and carditis but no residual valvular disease**, prophylaxis should extend for a period of 10 years or well into adulthood.
c. Indefinite antibiotic prophylaxis is recommended in **patients with valvular heart disease**.

3. The success of **oral prophylaxis** depends on the patient's understanding and adherence to the prescribed regimen. Oral agents are **more appropriate for patients at lower risk for rheumatic recurrences**. Some favor switching patients to oral prophylaxis when they have reached late adolescence or young adulthood and have remained free of rheumatic attacks for at least 5 years.
a. The preferred oral medication is penicillin V.
b. For **patients with true or suspected allergy to penicillin, sulfadiazine** can be used (Table 20.2). **Erythromycin** is an alternative.
c. It is important to keep in mind that even with optimal patient adherence, the **risk of recurrence is higher with an oral than with an intramuscular prophylactic regimen**.

C. Endocarditis prophylaxis. Updated guidelines from the American Heart Association published in 2007 recommend against routine prophylaxis for endocarditis in patients with rheumatic valvular disease undergoing dental or other procedures. Antibiotic prophylaxis is recommended only for patients with prosthetic valves, previous endocarditis, and certain forms of congenital heart disease and for heart transplant patients with vasculopathy (see Chapter 19).

D. Vaccines targeted against GAS. Several multivalent vaccines against GAS are currently in clinical trials. The M protein is the most promising target, but vaccine development has been complicated because there are multiple M-protein subtypes that are rheumatogenic. The use of a vaccine may prevent pharyngeal colonization, thereby removing population reservoirs, which allow for endemic disease.

VII. SCREENING

A. Screening in endemic areas. Given the significant burden of rheumatic heart disease, screening children and young adults has proven useful for those in endemic areas.

1. Screening generally involves three components: (1) eliciting a history of acute RF, (2) physical examination, and (3) echocardiography. Two screening approaches have been described in high-risk populations. First, physical examination including auscultation for murmur is followed by echocardiographic confirmation in those found to have a murmur. Alternatively, portable echocardiography is used for all followed by clinical examination of abnormal cases. Because auscultation has been shown to be clinician dependent and crude in detecting valve pathology, many cases of rheumatic heart disease go unidentified, favoring the echocardiographic approach to screening.

ACKNOWLEDGMENTS: *The author thanks Drs. Stephen Gimple, Simone Nader, and Mohammed Nasir Khan for their contributions to earlier editions of this chapter.*

SECTION IV

Arrhythmias

EDITOR

Thomas D. Callahan

CHAPTER 21

Omeed Zardkoohi

Tachyarrhythmias

I. INTRODUCTION. Tachyarrhythmias have been classically categorized by their location and mechanism. Tachyarrhythmias can originate from ventricular tissue (ventricular tachycardia) or, alternatively can originate from or involve supraventricular tissue (supraventricular tachycardia). The three mechanisms of tachyarrhythmias include abnormal automaticity, triggered activity, and reentry.

A. Abnormal automaticity. Automaticity refers to the ability of cardiac tissue to spontaneously generate pacemaker activity. There are both normal and abnormal sources of automaticity.

1. An example of **normal** accelerated automaticity is the rapid firing rates of a normal pacemaker focus, such as the sinus node (SN), atrioventricular (AV) node, or Purkinje system due to ischemia, metabolic disturbance, exercise, or pharmacologic manipulation. A clinical example would be accelerated **sinus tachycardia** or **junctional rhythm**.
2. Abnormal automaticity refers to tissues that under normal circumstances do not demonstrate automaticity, but can become automatic in the setting of ischemia, metabolic disturbance, or pharmacologic manipulation. Overall, abnormal automaticity is responsible for < 10% of tachyarrhythmias. These latent or ectopic loci of cells generate automatic, spontaneous impulses that usurp control of the cardiac rhythm. These usually have a warm-up and cool-down period and cannot be induced by programmed electrical stimulation. A clinical example would be **accelerated idioventricular** rhythm (see Section IV.C.1) or **multifocal atrial tachycardia** (see Section **II.F**).

B. Triggered activity refers to pacemaker activity that is dependent on afterdepolarizations from a prior impulse or series of impulses. Afterdepolarizations are oscillations in the membrane potential. If these reach the critical threshold for depolarization of the surrounding cardiac tissue, they may trigger an action potential, thereby precipitating further afterdepolarizations and perpetuating the pacemaker activity. The two categories of afterdepolarizations are early and delayed.

1. Early afterdepolarizations (EADs) occur before repolarization of the cardiac tissue is completed (during phase 3 of the action potential) and may be the mechanism responsible for the ventricular arrhythmias of the **long QT syndromes (LQTSs)**, as well as **torsade de pointes** ("twisting of the points") produced by class I and class III antiarrhythmics, sympathetic discharge, and hypoxia. Antibiotics such as macrolides, certain azole antifungal agents, some psychotropic medications such as haloperidol, and several nonsedating antihistamines have been shown to produce EADs. Rapid heart rates and the administration of magnesium have been shown to suppress EADs.
2. Delayed afterdepolarizations (DADs) occur after the repolarization of the surrounding tissue is complete (during phase 4 of the action potential) and are thought to be the mechanism of triggered atrial tachycardia, arrhythmias of **digitalis toxicity**, and rare ventricular tachycardias (VTs) responsive to calcium channel blockers. These have been demonstrated in various cardiac issues, including

parts of the conducting system, myocardial cells, and valve tissues. Increases in intracellular calcium are associated with DADs, such as those caused by digitalis preparations or excessive sympathetic stimulation. Drugs that block the influx of calcium (such as calcium channel blockers and β-blockers) and drugs that decrease the sodium current (such as lidocaine and phenytoin) suppress the occurrence of DADs, whereas rapid heart rates augment DADs.

C. Reentry. **Reentry is the most common cause of tachyarrhythmias**. In order for reentry to occur, **three conditions** must be met:

1. Two functionally distinct conducting pathways must connect to form a circuit.
2. Unidirectional conduction block occurs in one of the pathways due to differences in refractory periods (block occurs in pathway with the longer refractory period).
3. Slow conduction occurs down the unblocked pathway (which has the shorter refractory period), allowing the blocked pathway time to recover excitability and sustain the arrhythmia.

Reentrant circuits can occur in the sinus node, the atrium, the AV node, between the atrium and ventricle via bypass tracts, and within the ventricle itself. The typical substrate for malignant reentry in the ventricle is **scar or ischemia**, which can produce regions in the heart that **depolarize and repolarize heterogenously**. Therefore, the impulse can spread to an area that has already repolarized after being previously depolarized. This can set up a circular movement of the impulse resulting in sustained tachyarrhythmias such as VT. Reentry can typically be induced by premature electrical stimulation during electrophysiologic testing.

Elucidation of the mechanisms of tachyarrhythmias has led to the development of catheter-based treatment strategies and more advanced medical therapy.

II. SUPRAVENTRICULAR TACHYARRHYTHMIAS

A. Sinus tachycardia

1. **Clinical presentation.** Sinus tachycardia manifests as sinus rhythm with a rate above 100 beats/min. Although the rate may be as high as 200 beats/min in younger individuals, it is generally **150 beats/min or less in older individuals**.
2. **Pathophysiology**
   - **a.** The SN is an epicardial structure that is located laterally near the junction between the superior vena cava and the right atrium. Under normal circumstances, the rate of SN discharge is governed by sympathetic and vagal stimulation.
   - **b.** Sinus tachycardia generally reflects **an underlying process, metabolic state, or effect of medication**. Fever, hypovolemia, shock, congestive heart failure (CHF), anxiety, pulmonary disease including pulmonary embolism, anemia, thyrotoxicosis, caffeine, nicotine, atropine, catecholamines, or withdrawal from alcohol or drugs (both therapeutic and illicit) can cause sinus tachycardia.
   - **c.** Sinus tachycardia can be appropriate, where it represents a normal physiologic response, **or inappropriate**, as in defects in vagal or sympathetic tone or an intrinsic problem with the SN itself.
   - **d.** The **clinical consequences of sinus tachycardia vary** based on the presence or absence of underlying heart disease. Patients with significant coronary artery disease (CAD), left ventricular (LV) dysfunction, or valve disease may not tolerate sinus tachycardia. Patients with inappropriate sinus tachycardia may experience significant symptoms such as palpitations, dyspnea, and/or chest pain.
3. **Diagnostic testing.** Electrocardiography is the primary diagnostic test. The main differential is between sinus tachycardia, sinus node reentry tachycardia (SNRT) (see Section **II.B**), and inappropriate sinus tachycardia. Inappropriate sinus tachycardia is characterized by the following features: **(a) heart rate > 100 beats/min, (b) P-wave axis and morphology during tachycardia similar or identical to that during sinus rhythm, (c) exclusion of secondary causes**

of sinus tachycardia, (d) exclusion of atrial tachycardias, and (e) symptoms clearly documented to be related to resting or easily provoked sinus tachycardia.

4. Therapy is generally directed at the elimination of the underlying cause whenever possible.
   a. If withdrawal from a therapeutic medication is suspected, then reinstitution or slow tapering of this medication can be attempted, if clinically appropriate.
   b. In the case of **inappropriate sinus tachycardia, β-blockers and calcium channel blockers** may be necessary to control the heart rate.
   c. In **medically refractory cases, catheter ablation for sinoatrial nodal modification** may have to be considered.

B. SNRT accounts for 5% to 10% of all supraventricular tachyarrhythmias.

1. **Clinical presentation.** SNRT is most frequently seen in patients with structural heart disease or CAD, especially in inferior myocardial infarctions (MIs). The rate varies from 80 to 200 beats/min. SNRT's characteristic abrupt onset and termination (paroxysmal nature) along with its ability to be induced and terminated by pacing imply that the underlying mechanism is reentry and distinguish it from sinus tachycardia and inappropriate sinus tachycardia.
2. **Pathophysiology.** Reentry occurs within or adjacent to the SN and then conducts via the normal conduction pathway to the rest of the heart. The morphology of the P wave is identical to the underlying sinus morphology. Block at the AV node may occur, but it does not slow the tachycardia. In fact, a Wenckebach-type block often occurs with this rhythm. The development of a bundle branch block does not affect the cycle length or the PR interval.
3. **Therapy.** Vagal maneuvers or adenosine may successfully terminate this arrhythmia. **Rapid atrial pacing** can be used to induce and terminate this tachycardia. Various agents such as β-blockers, calcium channel blockers, and digoxin may help prevent recurrences. SN ablation or modification is rarely necessary.

C. Atrial fibrillation (AF) is the most common sustained arrhythmia, occurring in up to 1% of the general population. The prevalence of AF increases with age, affecting up to 10% of the population older than 80 years (see Chapter 24).

D. Atrial flutter. Atrial flutter is the **second most common of the atrial tachyarrhythmias**. Its reported incidence varies from 0.4% to 1.2% in hospital reports of electrocardiogram (ECG). The **clinical significance of atrial flutter is generally due to its association with AF** (with all of the attendant risks of AF) and/or its association with rapid rates of ventricular response.

1. **Clinical presentation.** The clinical presentation may vary widely depending on the presence of underlying heart disease, the ventricular rate, and the overall condition of the patient. It is **occasionally reported to persist for days** and, less commonly, for weeks or longer. Careful examination of the jugular venous pulse may reveal **frequent, regular a waves** that correspond to the atrial flutter rate. Like AF, it is **commonly seen after open heart surgery, as well as with other conditions commonly associated with AF**, such as pulmonary disease, thyrotoxicosis, atrial enlargement due to any cause including mitral/tricuspid valve disease, and SN dysfunction.
2. **Pathophysiology.** "Typical" atrial flutter is the **result of a macroreentrant circuit in the right atrium**. Atypical atrial flutter generally involves other macroreentrant circuits around scar tissue or surgical incisions.
   a. **In a typical atrial flutter, the reentrant circuit most commonly travels in a counterclockwise rotation** down the right atrial anterolateral free wall across the cavotricuspid isthmus (area of slow conduction) and up the interatrial septum. Clockwise rotation of this circuit may also be seen.

b. Atrial flutter has been classified into type I and type II based on the following characteristics:

(1) Type I atrial flutter can be terminated with rapid atrial pacing and typically has an atrial rate in the range of 240 to 340 beats/min in the absence of drug therapy.

(2) Type II atrial flutter cannot be terminated with rapid atrial pacing and typically has an atrial rate in the range of 340 to 440 beats/min in the absence of drug therapy.

(3) Types I and II are not synonymous with typical and atypical atrial flutters. Type I atrial flutter can include typical and atypical atrial flutters. Type II atrial flutter is less well characterized than type I with respect to etiology and therapy; therefore, **we refer to type I atrial flutter throughout this discussion**.

3. Laboratory examination

a. The **diagnosis can be difficult when the AV conduction is 2:1**, as the flutter waves may be superimposed on the QRS complex and/or the T waves. When the diagnosis is uncertain, one should **consider maneuvers or medications to slow the ventricular response**, thus revealing the atrial flutter complexes.

(1) Vagal maneuvers include carotid sinus massage and Valsalva maneuver. **Caution must be exercised** when attempting carotid sinus massage **in patients with known or suspected carotid disease** or vagal maneuvers in **patients with CAD who are at risk for ischemia**.

(2) Adenosine can be administered, 6 mg rapid intravenous push, followed by 12 mg if there is no response (a second 12-mg dose can be given if there is no response). The half-life of this medication is very short, approximately 9 seconds. This causes transient (lasting seconds), complete AV block. Alternative agents include the intravenous calcium channel blocking agents **verapamil and diltiazem** and the intravenous β-blockers **esmolol and metoprolol**. Patients should be connected to a transcutaneous pacing device during the administration of this medication for reasons of safety.

(3) The clinician can place and record from a **transesophageal electrode** or record from a **temporary atrial epicardial pacing wire** (placed at open heart surgery). This results in an ECG with clearer atrial complexes and thus simplifies diagnosis. This strategy also allows a method of delivering rapid atrial pacing in an attempt to terminate the atrial flutter.

b. On the surface ECG, typical counterclockwise atrial flutter shows the **classic negatively directed "sawtooth" waveform** in the inferior leads (II, III, and aVF) (Fig. 21.1). Conversely, the atrial depolarizations are positive in these leads in clockwise atrial flutter (Fig. 21.2).

c. The **atrial rate** in the absence of drug therapy is **240 to 340 beats/min**.

d. The **QRS complex should be the same as that seen during sinus rhythm** although aberrant conduction may occur, and the QRS may be slightly distorted by the atrial flutter waves.

e. The **ventricular response** can be irregularly irregular, due to varying degrees of block (2:1, 4:1, and so on), but is more **typically regular as a fixed ratio of the flutter rate**.

4. Therapy

a. Medical therapy differs very little from that for AF (see Chapter 24).

(1) Control of the ventricular response rate with a β-blocker, a calcium channel blocker, or digoxin is critical prior to initiating therapy with agents such as the class IA or IC agents. The class IA or IC agents either enhance AV nodal conduction through their vagolytic effects, thereby enabling 1:1 (AV) conduction, or slow the atrial rate to a point where 1:1 conduction is facilitated.

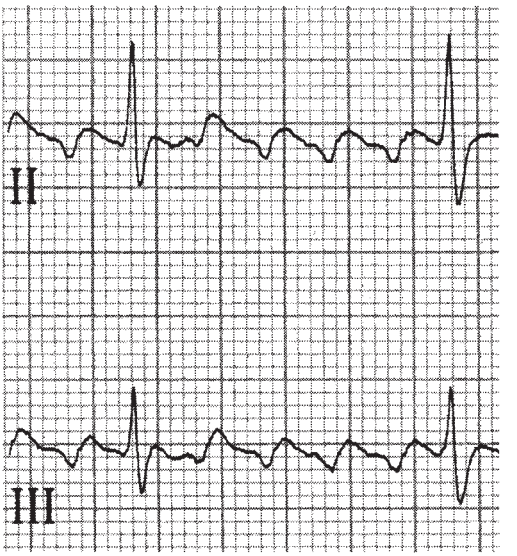

FIGURE 21.1 "Typical" atrial flutter, leads II and III.

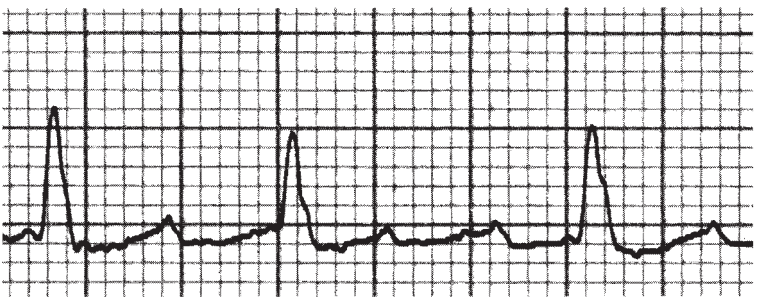

FIGURE 21.2 "Atypical" atrial flutter, lead II.

(2) The conversion from atrial flutter to AF after cardioversion is substantially reduced by the administration of antiarrhythmic drugs prior to direct current cardioversion (DCC), thereby increasing the chance of converting to sinus rhythm.

(3) **Anticoagulation.** There are no prospective data looking at the incidence of thromboembolic events with atrial flutter. However, retrospective data suggest an increased incidence of thromboembolic events. Recent ACCP (2004) and ACC/AHA/ESC (2006) guidelines recommend managing anticoagulation in atrial flutter in a manner similar to that for AF, including cardioversions. Optimal management is unclear and often needs to be individualized with the patients' profile for thromboembolic risk dictating the type and duration of therapy. We treat atrial flutter in a manner similar to that used for AF with regard to anticoagulation.

b. Direct current cardioversion

(1) DCC is the preferred and most effective therapy for most patients. The procedure is detailed in Chapter 59. A starting energy as low as 25 to 50 J is often effective. Because DCC may result in conversion from atrial flutter to AF, a second shock is sometimes necessary to convert AF to sinus rhythm.

(2) Rapid atrial pacing should be considered as the **first line of therapy for all patients who have epicardial atrial pacing wires in place after open heart surgery**. It may be considered via a transesophageal pacing lead or via a transvenously placed pacing lead in patients for whom DCC fails or who are not candidates for DCC. **Before attempting to rapidly pace the atria, it must be confirmed that ventricular capture is not inadvertently occurring** by first pacing at a relatively slow rate while observing for such a phenomenon. Once this is confirmed, the atrium is paced at a rate of 10 to 20 beats/min faster than the underlying atrial flutter rate. Once atrial capture is attained, the rate is increased steadily until the hallmark negative-sawtooth waveform converts to a positive waveform. The pacing is then either halted abruptly or slowed rapidly to an acceptable atrial pacing rate. In cases that require extremely rapid rates of pacing (> 400 beats/min) or high amplitudes of pacing stimulus strength (> 20 mA), there is an increased tendency for the atrial flutter to convert to AF. **When pacing via a transesophageal lead, a higher stimulus strength (up to 30 mA) may be necessary**. **Because this type of pacing can be quite painful**, a sufficient energy to convert the atrial flutter should be used initially to minimize the conversion attempts.

(3) Percutaneous therapy. Radiofrequency ablation (RFA) of the cavotricuspid isthmus is often curative, with an efficacy > 90% for the long-term elimination of atrial flutter. Despite the high success rate of catheter-based therapy, a significant number of patients may subsequently develop AF.

E. Atrial tachycardias. This term encompasses a number of different types of tachycardias that originate in the atria. These tachycardias account for between10% and 15% of the tachycardias seen in older patients, usually in the setting of structural or ischemic heart disease, chronic obstructive pulmonary disease, electrolyte imbalances, or drug toxicity (particularly digitalis).

1. Clinical presentation. These tachycardias are **infrequently seen in younger, healthy patients without underlying heart disease**. They are **typically paroxysmal**, but if incessant they can lead to a tachycardia-induced cardiomyopathy.

2. Diagnostic testing

a. ECG

(1) The **P-wave axis** or morphology is usually different from that of sinus rhythm. One exception is atrial tachycardias originating from the right superior pulmonary vein, which is anatomically close to SN. The axis can be used to predict the origin of the atrial tachycardia.

(2) Atrial rhythm is regular, except with automatic atrial tachycardia, which displays a warm-up period (see Section **II.E.3.b**).

(3) A **QRS complex that is generally identical to sinus rhythm** (QRS can be wide if aberrant conduction occurs) follows each P wave.

(4) PR interval is within normal limits or prolonged.

(5) Nonspecific ST-T–wave changes may be present.

(6) When an AV block is present, there is an **isoelectric baseline** between P waves in all leads.

b. Electrophysiologic study has become critical in determining the underlying mechanism of these tachycardias, as the clinical differences are subtle and overlapping.

3. **Subclassifications.** The current subclassifications are **based on mechanisms** and include automatic atrial tachycardia, triggered atrial tachycardia, and intra-atrial reentry.
   a. Intra-atrial reentry is usually a disorder **seen in those with underlying heart disease or history of atrial arrhythmia**, such as AF or atrial flutter. The mechanism is not well understood. The ventricular rate is typically 90 to 120 beats/min due to the frequent occurrence of 2:1 AV block, such that hemodynamic effects are generally minimal. This rhythm can be difficult to distinguish from other supraventricular tachyarrhythmias. One clue is that despite any AV conduction block, the rhythm continues. The ability to terminate with adenosine and β-blockers is variable. **RFA may be effective**, with success rates **>** 75%. **Antiarrhythmics** (the same drugs as for AF and atrial flutter) **have been disappointing in the prevention of recurrence**.
   b. Automatic atrial tachycardia appears to be generated by an ectopic atrial focus, which usually arises from regions around the crista terminalis in the right atrium and around the base of the pulmonary veins in the left atrium. The mechanism is not well understood. Automatic atrial tachycardia is **seen more often in younger patients**, displays a **warm-up phenomenon** (the supraventricular tachyarrhythmia accelerates after its initiation), **does not respond to vagal maneuvers, and is more likely to be incessant**. Automatic atrial tachycardia can be induced with treadmill testing or with administration of isoproterenol. Atrial stimulation during electrophysiologic study has no effect on either initiating or terminating this arrhythmia. **Propranolol** has been used successfully to suppress automatic atrial tachycardia. **Catheter ablation is the preferred therapy when the tachycardia is incessant**. Although adenosine may transiently slow automatic atrial tachycardia, it is unlikely to terminate it. Likewise, verapamil has been used without success.
   c. Triggered atrial tachycardia is the least common of the atrial tachycardias and is virtually never incessant. It is more likely to appear in **older individuals**. It can be induced with rapid atrial pacing and is cycle length–dependent. The mechanism of triggered atrial tachycardia is thought to be due to DADs (see Section **I.A.2**) secondary to digitalis toxicity or sympathetic discharge. Catecholamines may play a role in the initiation of this arrhythmia, and thus exercise testing and isoproterenol may provoke it. Verapamil and adenosine have been shown to terminate triggered atrial tachycardia. β-Blockers have been less effective. **RFA** is preferred when the tachycardia is very symptomatic and not responsive to medication.

F. Multifocal atrial tachycardia

1. **Clinical presentation.** This atrial arrhythmia is uncommon and estimated to occur in 0.37% of hospitalized patients. The atrial rate is generally 100 to 130 beats/min. It occurs most often in elderly, critically ill patients and is frequently **associated with concurrent pulmonary disease, particularly chronic obstructive pulmonary disease**. It may also be seen in CHF and can degenerate into AF.
2. **Pathogenesis and diagnostic tests.** The mechanism appears to be abnormal automaticity or triggered activity arising from distinct atrial sites. The diagnosis requires the following criteria: (1) atrial rate > 100 beats/min, (2) P waves with three or more different morphologies, (3) varying P-P, P-R, and R-R intervals, and (4) the P waves separated by isoelectric intervals. Loss of AV conduction of each P wave is uncommon, making it possible to distinguish multifocal atrial tachycardia from AF.
3. **Therapy is directed at the underlying illness, with little role for antiarrhythmics.** Calcium channel blockers in high doses may be useful, or amiodarone when antiarrhythmic therapy is deemed necessary. Maintenance of electrolyte balance, particularly potassium and magnesium, may suppress the occurrence of multifocal atrial tachycardia.

G. Atrioventricular nodal reentrant tachycardia (AVNRT)

1. **Clinical presentation.** AVNRT usually has a narrow QRS complex with a ventricular rate typically in the range of 150 to 250 beats/min, although faster rates are infrequently observed. AVNRT is generally seen in patients without underlying heart disease. Palpitations and dyspnea are common presenting complaints. Angina, CHF, and rarely shock may be seen in those with a history of underlying heart disease. Syncope may occur due to rapid ventricular rates or due to asystole or bradycardia seen occasionally when this tachycardia terminates.
2. **Pathophysiology.** The mechanism in AVNRT appears to be a reentrant circuit composed of separate fast and slow atrial pathways involving the AV node. In 50% to 90% of patients with "typical" AVNRT, the antegrade conduction to the ventricles travels over the slow pathway and the retrograde conduction to the atria occurs over the fast pathway. The initiating event may be either a premature atrial complex (PAC) or a premature ventricular complex (PVC). The PAC blocks the fast pathway antegradely and conducts down the slow pathway, then backs up the fast pathway after it has repolarized. Less commonly, a PVC conducts retrogradely to the atria via the fast pathway and then returns to the ventricles via the slow pathway. In the remaining 5% to 10% of patients, with atypical AVNRT, the antegrade conduction is down the fast pathway and retrograde via the slow pathway. The cycle length is thus dependent on the conduction velocity of the slow pathway, since the fast pathway generally has rapid conduction. Termination of the tachycardia is often the result of a block in the slow pathway. AV dissociation may develop during the tachycardia because the ventricles are not involved in the reentry circuit. This does not affect the rate of tachycardia nor does the development of bundle branch block.
3. **Laboratory features and diagnosis.** P waves are generally hidden within the QRS complex or at the terminal portion of the QRS in typical AVNRT. This may be visible as a small pseudo-R′ in lead V_1 or small negative deflections in the inferior leads, as depolarization of the atria occurs simultaneously with ventricular depolarization. The RP segment is generally < 100 milliseconds. AVNRT is often induced abruptly by a PAC and its termination, which also tends to be abrupt, is often followed by a retrograde P wave. The termination may be followed by a brief period of asystole or bradycardia before the SN recovers from its tachycardia-induced suppression. The cycle length may vary, especially at the beginning and at the end of the tachycardia. This variation reflects the variable antegrade AV nodal conduction time. Vagal maneuvers may slow or terminate this tachycardia.
4. **Therapy.** Presently, the success and safety of percutaneous catheter ablation have allowed this approach to be considered equally with medical therapy as first-line therapy for long-term management of AVNRT. The decision about treatment approach should be individualized according to the characteristics of each patient and his or her arrhythmic patterns.
   a. RFA has the advantage of curing the arrhythmia in the majority of instances and eliminating the need for long-term suppressive therapy with medications. Cure rates with catheter ablation for AVNRT are in excess of 95%.
   b. **Medical therapy.** Medications that suppress AV nodal conduction such as β-blockers, calcium channel blockers, digoxin, and adenosine all slow or block conduction in the antegrade slow pathway, whereas class IA and class IC antiarrhythmic drugs slow the conduction in the retrograde fast pathway. Adenosine may be considered as first-line drug therapy for acute termination of AVNRT. This medication is available in an intravenous form only and has a very short half-life of about 9 seconds. The use of intravenous or oral β-blockers or calcium channel blockers is an alternative if adenosine is unsuccessful. The onset of action of digoxin limits its usefulness in terminating these arrhythmias, although it may be useful to prevent recurrences. Recurrences may be prevented in patients

with frequent sustained episodes with any of the above-mentioned agents except adenosine. Antiarrhythmic drug therapy is not routinely necessary or desirable for AVNRT, given the high success rates and low complication rates for catheter ablation.

c. DCC should be considered for patients whose disease is unstable or highly symptomatic. Low energies of 10 to 50 J are usually sufficient to terminate AVNRT.

H. Atrioventricular reentrant tachycardia (AVRT)

1. **Clinical presentation.** Similar to AVNRT, this is another example of an AV nodal–dependent supraventricular tachycardia (SVT). AVRT usually has a narrow QRS with ventricular rates similar to those of AVNRT, although it more often tends to have a ventricular rate > 200 beats/minute. The clinical features are very similar to those of AVNRT but are distinct on an electrophysiologic basis.
2. **Pathophysiology.** The mechanism in AVRT relies on the presence of an accessory pathway as one portion of the circuit and the AV node as the other portion. The atrium and the ventricle on the same side as the accessory pathway are necessary components of the circuit. AVRT may be orthodromic or antidromic. Orthodromic AVRT usually has a narrow complex that uses the AV node as the antegrade limb and the accessory pathway as the retrograde limb of the circuit. Antidromic AVRT has a wide complex that is the opposite of the orthodromic variety, such that the accessory pathway serves as the antegrade limb and the AV node as the retrograde limb of the circuit. AVRT is most often of the orthodromic type. Accessory pathways may be "concealed" (inapparent by ECG) because of having only retrograde (V to A) conduction properties or "manifest" (apparent on ECG as delta waves, i.e., Wolff-Parkinson-White [WPW] pattern). **Unlike AVNRT, the AVRT circuit must involve one of the ventricles; therefore, the development of bundle branch block on the side ipsilateral to the accessory pathway can prolong the ventricular to atrial conduction time and often the cycle length of the tachycardia**. Bundle branch block, particularly left bundle branch block (LBBB), occurs more commonly in AVRT than in AVNRT. AVRT can be distinguished from AVNRT by electrophysiologic study. The presence of AV or ventriculoatrial (VA) block with continuation of the tachycardia should exclude the presence of an accessory AV pathway.
3. **Laboratory features and diagnosis.** The P waves of AVRT are frequently inscribed on the ST segment or T wave, as the atrial depolarization and ventricular depolarization are in series rather than in parallel. The RP segment is generally > 100 milliseconds. Orthodromic AVRT is more common, accounting for about 95% of all AVRTs, whereas antidromic AVRT accounts for only about 5%. Orthodromic AVRT is usually characterized by a narrow QRS complex as opposed to antidromic AVRT, which is characterized by a wide QRS complex.
4. **Therapy.** See the discussion of therapy for WPW syndrome (Section **I.4**).

I. Preexcitation syndromes. Preexcitation was originally used to describe the premature activation of ventricle in patients with WPW. The term has broadened to include all conditions in which antegrade ventricular activation or retrograde atrial activation occurs partially or totally via an anomalous pathway distinct from the normal cardiac conduction system. The incidence of preexcitation on ECG is approximately 1.5 per 1,000 cases, most of which occur in otherwise healthy subjects without organic heart disease. About 7% to 10% of these patients have associated Ebstein's anomaly and are thus more likely to have multiple accessory pathways. There is a higher rate of preexcitation in males, with the **prevalence** decreasing with age, although the **frequency** of paroxysmal tachycardia increases with age.

1. **Clinical presentation.** Approximately 50% to 60% of patients with preexcitation report symptoms such as **palpitations, anxiety, dyspnea, chest pain or tightness, and syncope**. In approximately 25% of the cases, the disease will

become asymptomatic over time. Those patients older than 40 years whose disease has been asymptomatic are likely to remain symptom free. The absence of preexcitation on ECG despite the discovery of accessory pathways in patients with asymptomatic disease likely identifies a group of patients at low risk for developing symptoms.

2. **Pathophysiology.** Patients with preexcitation generally have an accessory pathway(s) that alters the conduction between the atria and the ventricles. These accessory pathways are likely congenital, as relatives of subjects with preexcitation have an increased incidence of preexcitation. AVRT is the most common mechanism associated with preexcitation (80% to 85%), with permanent junctional reciprocating tachycardia, Mahaim fiber tachycardia, and Lown-Ganong-Levine (LGL) syndrome accounting for the remainder.
   a. **WPW syndrome.** The basic abnormality lies in the existence of an accessory pathway of conducting tissue, outside of the normal conducting system, which connects the atria and the ventricles. This accessory pathway permits the atrial impulse to bypass the normal pathway through the AV node to the ventricles. In the past, these accessory pathways have been referred to as "bundles of Kent." An impulse from the atria can be conducted down both the accessory pathway and the AV node, arriving at the ventricle at nearly the same time. This results in preexcitation of the ventricle, which is really a fusion beat, as a portion of the ventricle is activated via the accessory pathway (giving rise to the delta wave; Fig. 21.3) and the remainder of the ventricle is activated by the normal activation pathway. If antegrade conduction occurs exclusively via the accessory pathway, the resultant QRS is maximally preexcited and is a wide complex. These accessory pathways may conduct rapidly, but frequently have longer refractory periods than the AV node. The inciting event for AVRT is frequently a PAC that is blocked in the accessory pathway and that conducts to the ventricles via the AV node, which has recovered more rapidly. The resultant QRS complex in this instance is normal in appearance. After the QRS complex, the accessory pathway has had sufficient time to recover excitability, and the impulse thus conducts retrogradely to the atria. A small but significant percentage (5% to 10%) of patients have multiple accessory pathways.
   b. Permanent junctional reciprocating tachycardia is a variant of AVRT. It is often an incessant supraventricular tachyarrhythmia with an unusual accessory pathway. Here, the accessory pathway behaves like the AV node in that it displays decremental retrograde conduction properties. Thus, the faster the stimulation of such an accessory pathway, the slower the conduction through the pathway. The accessory pathway is most often located in the posteroseptal region and acts as the retrograde limb of the reentrant circuit. The VA conduction is slowed by the decremental nature of the accessory pathway. Due to the incessant nature of this tachycardia, a tachycardia-induced cardiomyopathy may result.
   c. **Mahaim fiber tachycardias are another variant of reentrant tachycardia.** The two most common varieties that are recognized are **atriofascicular and fasciculoventricular.** In the former, the accessory pathway is located within a few centimeters of the AV node and inserts into the right bundle branch. The reentrant tachycardia conducts antegrade via the accessory pathway, resulting in an LBBB morphology with left-axis deviation. The retrograde circuit is via the AV node. In the second form of Mahaim reentry, the accessory pathway arises in the His-Purkinje fibers and allows bypass of the distal conducting system.
   d. LGL syndrome is diagnosed by the presence of a short PR interval and a normal QRS complex on the surface ECG. LGL syndrome likely represents one

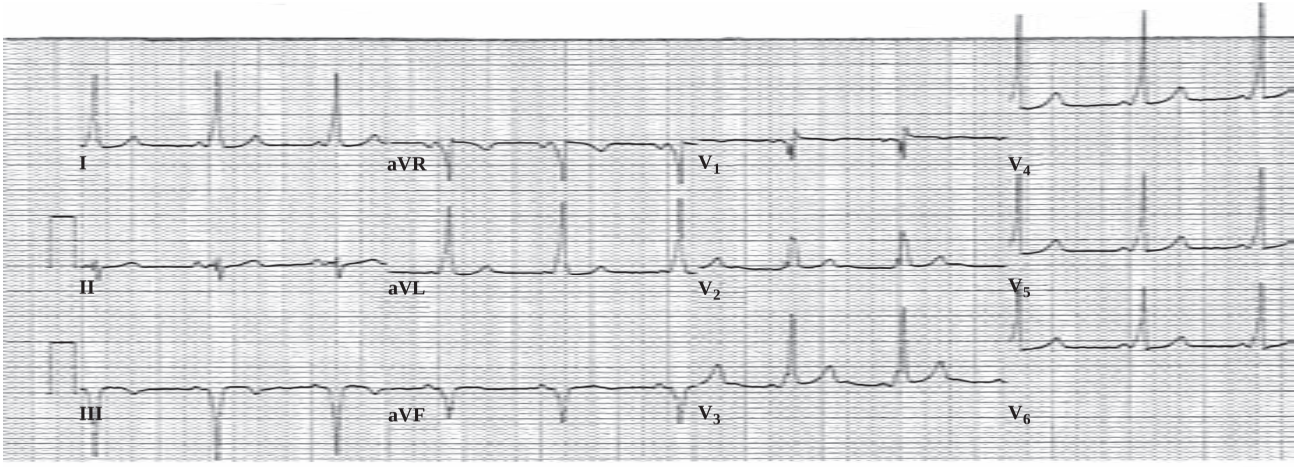

FIGURE 21.3 Wolff-Parkinson-White syndrome, with widespread delta waves seen at the upstroke of the QRS complexes.

end (enhanced) of the normal spectrum of AV nodal conduction properties, but in some cases it is impossible to exclude a distinct perinodal accessory pathway or an abnormality in conduction characteristics of the AV node. It is uncertain if this abnormality in AV conduction is itself associated with arrhythmias.

3. Diagnostic testing

a. The following electrocardiographic criteria are suggestive of an accessory pathway consistent with a WPW pattern. The WPW syndrome occurs in the setting of the WPW pattern and SVT.

(1) The PR interval is short, typically < 120 milliseconds.

(2) The QRS complex exceeds 120 milliseconds, with some leads showing the characteristic slurred upstroke known as a delta wave (Fig. 21.3) and a normal terminal QRS portion.

(3) The ST-T segment is directed opposite to the major delta and QRS vectors.

b. The most commonly seen tachycardia in WPW syndrome is characterized by a normal QRS with a regular rate of 150 to 250 beats/min. Onset and termination are abrupt.

c. Localization of accessory pathway. The **surface ECG** may provide information that allows localization of the accessory pathway. The simplest classification is that of type A or type B. **Type A** has a large R wave in lead V_1. It is due to a left-sided accessory pathway, which permits preexcitation to the posterobasilar segment of the left ventricle. **Type B** has an S or QS in lead V_1 and is due to a right-sided accessory pathway. When present, the morphology of a retrograde P wave can be helpful in predicting the location of the accessory pathway. More elaborate algorithms for localization are available. The **most precise localization method is electrophysiologic study** with ventricular pacing or during orthodromic AVRT (the latter condition is especially helpful as there is VA conduction purely through the accessory pathway, and fusion with VA conduction through the AV node is, therefore, avoided). A positive P wave in lead V_1 during supraventricular tachyarrhythmia suggests a left free wall pathway, whereas a negative P wave suggests a right-sided pathway.

d. Risk stratification should be considered for patients with WPW pattern or ventricular preexcitation according to ECG findings. The appearance or disappearance of preexcitation on **serial ECGs is of no predictive value**. However, **the intermittent loss or appearance of preexcitation on a beat-to-beat basis is indicative of lower risk**. This may be assessed with ambulatory Holter monitoring during usual activities or with formal exercise stress testing. Such intermittent preexcitation suggests a pathway without the ability for rapid AV conduction and, therefore, lower risk of sudden cardiac death (SCD). However, the reverse is not necessarily true in that most patients with persistent preexcitation may still be at low risk for SCD, but these patients cannot be distinguished from those at risk. As the greatest danger to patients with preexcitation may be the development of AF, **the induction of AF may be most useful in risk stratification**. This can be done via transesophageal pacing; however, electrophysiologic study is the procedure of choice for risk stratification in patients with persistent ventricular preexcitation.

4. Therapy

a. Emergency management of acute tachycardia episodes. A patient ***demonstrating hemodynamic instability or extreme symptomatology should be cardioverted rapidly***. Stable patients may be treated medically.

(1) Normal QRS width. Both types of AVRT (orthodromic and antidromic) are AV node–dependent and thus respond to AV nodal blocking therapies. Although it is reasonable to use vagal maneuvers and AV nodal

blocking medications acutely in patients presenting with a narrow QRS (immediate synchronized DCC should be available should the rhythm degenerate), it is not safe in patients when they present with a wide QRS. Atrial pacing, either transvenous or transesophageal, is also quite efficacious for terminating these types of tachycardias. Adenosine, although effective in treating orthodromic and antidromic AVRTs, may induce AF in up to 15% of cases and should, therefore, be used with caution. In patients with WPW syndrome, AF is a potentially life-threatening arrhythmia, especially when the accessory pathway has a short antegrade refractory period capable of rapid ventricular conduction.

(2) **Wide QRS width.** Patients with accessory pathways can present with wide QRS complex resulting from **(1)** orthodromic AVRT with aberrant conduction; **(2)** antidromic AVRT; or, **most importantly**, **(3)** atrial arrhythmias (atrial tachycardia/atrial flutter/atrial fibrillation) with antegrade conduction down an accessory pathway. Since it is often initially impossible to determine the mechanism of a wide QRS complex in patients with an accessory pathway, they should be treated with agents that slow conduction in the accessory pathways (procainamide, flecainide, sotalol, or amiodarone). Because atrial arrhythmias with antegrade accessory pathway conduction are **not** AV node–dependent, AV nodal blocking therapies are ineffective and potentially very dangerous. β-Blockers, calcium channel blockers, digoxin, and adenosine should be avoided in patients presenting with wide complex tachycardias (WCTs), as they may encourage preferential conduction down accessory pathways and accelerate ventricular rates, precipitating ventricular fibrillation (VF). **If the tachycardia persists, synchronized DCC** is the treatment of choice. Energies of at least 200 J are likely to be required.

(3) If the patient develops AF, it has been observed that **definitive therapy for the AV reentrant circuit, such as ablation of the accessory pathway, often results in the prevention of future episodes of AF**.

b. Long-term management

(1) **Priority of therapy.** Patients whose disease is asymptomatic at diagnosis are at low risk for sudden death. As such, it may not be justified to pursue medical or ablative therapy in these patients unless there is a family history of sudden death or the patients are competitive athletes or are in a high-risk occupation. Patients whose disease is symptomatic or who have a history of AF or aborted sudden death may be at higher risk, and such patients warrant further study.

(2) **Medical therapy.** Medical therapy may be **appropriate for those with increased risk but no prior symptoms, those with accessory pathways located near the normal conduction pathway that might develop AV block with RFA**, or those at increased risk from invasive procedures. Single-drug therapy may be attempted with **amiodarone, sotalol, flecainide, or propafenone**. These drugs work to slow conduction in both the accessory pathway and the AV node. **Combination therapy** can be accomplished with drugs that work on the AV node (calcium channel blockers, β-blockers) and with drugs that work exclusively on the accessory pathway (class IA antiarrhythmics).

(3) **Percutaneous therapy.** RFA is effective 85% to 98% of the time, depending on the location of the accessory pathway. Recurrence rates are approximately 5% to 8%. Catheter ablation should be considered for any patient at high risk, patients with symptoms or tachycardias refractory to medical therapy, those who have intolerance to medical therapy, and those with high-risk occupations such as pilots.

J. Atrial premature depolarizations (APDs). APDs are premature depolarizations that arise from a region other than the SN. The P-wave morphology and PR interval may be different from the sinus P wave and normal P interval, depending on the location and timing of the APD.

1. **Clinical presentation.** APDs are usually asymptomatic and in isolation are considered to be benign. Some patients may feel palpitations or skipped beats. If there is atrial bigeminy with each APD causing AV block, patients may develop symptoms of bradycardia. APDs may trigger SVT (AVNRT, AVRT, and atrial tachycardia) or AF in patients with the electrical and structural substrate for these arrhythmias. APDs increase in frequency as patients age and may be more frequent in patients with mitral valve disease, LV dysfunction, hypertrophic cardiomyopathy (HCM), mitral stenosis, pulmonary disease, and renal failure. Stress, alcohol and caffeine consumption, and smoking can promote APDs. However, APDs also occur in healthy individuals with structurally normal hearts and without significant external exposures (caffeine, alcohol, and stress). Although one study showed a correlation between the frequency of APDs within a 24-hour period and the risk of stroke in men, it is unclear what percentage of these men developed AF. Furthermore, in the ARIC (Atherosclerosis Risk in Communities) study which followed patients with APDs and ventricular premature depolarizations (VPDs), patients with APDs only did not have increased incidence of SCD.
2. **Pathophysiology.** APDs may be caused by a variety of mechanisms, including reentry, triggered activity, and increased automaticity. Reentry is thought to be the most common mechanism.
3. **Therapy.** Asymptomatic individuals do not need treatment for APDs. For symptomatic patients, β-blockers and class IA, class IC, and class III antiarrhythmic drugs may be considered, although no randomized controlled trials have been performed in this patient population.

III. VENTRICULAR TACHYARRHYTHMIAS.

Ventricular tachyarrhythmias, including monomorphic VT, polymorphic VT, and VF, account for up to 80% of SCD.

A. Ventricular tachycardia. VT is defined as three or more consecutive QRS complexes of ventricular origin at a rate exceeding 100 beats/min. The various types of VTs and their course of disease are discussed in Section **IV**.

1. **Clinical presentation.** The presentation is variable and depends on the clinical setting, the heart rate, the presence of underlying heart disease, and other medical conditions. Some patients have no or minimal symptoms, whereas others may present with syncope or sudden death. The loss of normal AV synchrony may cause symptoms in patients with decreased cardiac function at baseline. Heart rates < 150 beats/min are surprisingly well tolerated in the short-term, even in the most compromised individuals. Exposure to these rates for more than a few hours is likely to be associated with heart failure in patients with poor ventricular function, whereas those with normal ventricular function may tolerate prolonged periods at such rates. The range of 150 to 200 beats/min is tolerated variably, according to the factors noted previously. Once the rate reaches and exceeds 200 beats/min, there are symptoms in virtually all patients. **Nonsustained ventricular tachycardia** (NSVT) is generally defined as a VT of duration < 30 seconds. VT is **generally regular in rate and appearance**, although it can be polymorphic in appearance, slightly irregular with respect to rate, and may have capture and/or fusion beats within it.
2. **Differential diagnosis.** VT needs to be distinguished from **supraventricular tachyarrhythmia with aberrant intraventricular conduction, bundle branch block, and morphologic changes of the QRS complex secondary to metabolic derangement or pacing**.

a. **Brugada criteria.** Distinguishing VT from **supraventricular tachyarrhythmia with aberrancy** can be challenging. Various criteria have been proposed. A good rule of thumb **is that any WCT in a patient with ischemic heart disease is VT until proven otherwise**. Some have reported that > 80% of WCTs in such patients are VTs. The **algorithm proposed by Brugada may be helpful in making this distinction, and the algorithm is both sensitive** (99%) **and specific** (96.5%) in patients without a preexisting bundle branch block. As shown in Figure 21.4, a stepwise approach is applied. In the first step, the precordial leads are examined for the presence or absence of an RS complex. If an RS is uniformly absent, VT is established. If an RS is present in at least one precordial lead, one moves to the second step, which is measuring the interval from the onset of the QRS complex to the nadir of the S wave. If this distance is > 100 milliseconds in at least one precordial lead, then the diagnosis of VT is made. If there is no RS interval > 100 milliseconds, the third step is used. In the third step, one looks for evidence of AV dissociation. If there are more QRS complexes than P waves, then the diagnosis is VT. If not, then one moves to the fourth step, which involves examining the morphology of the QRS in the precordial leads V_1 and V_6. If the morphology criteria for VT (Fig. 21.5) are present in these leads, then the diagnosis of VT is established. If not, the diagnosis is supraventricular tachyarrhythmia with aberrant intraventricular conduction.

b. The Brugada criteria have been further refined to distinguish between VT and supraventricular tachyarrhythmia with antegrade conduction over an accessory pathway. After applying the preceding criteria, a second stepwise algorithm is applied (Fig. 21.6). This **second algorithm has a sensitivity of 75% and a specificity of 100% to diagnose VT and exclude preexcited tachycardia**. In the first step, leads V_4 to V_6 are examined to see if the QRS is predominantly negative. If so, then VT is favored. If not, then the second step, examining leads V_2 to V_6 for the presence of a QR complex in one or more of these leads, is applied. If there is a QR complex in any of these leads, then the diagnosis is VT. The third criterion, presence of AV dissociation, is 100% specific for VT. If there is no AV dissociation, then supraventricular tachyarrhythmia with antegrade accessory pathway conduction is favored.

c. A new criterion for differentiating VT from SVT was published in 2008 by Vereckei et al. (1), which boasts a > 90% accuracy in their cohort (Fig. 21.7). The rationale to use the new method was to simplify the approach by using one electrocardiographic lead (aVR) in a four-step, tree-like model. The method starts with identifying the presence of an initial R wave in aVR. If present, VT is diagnosed. If not, then the next step is to assess the presence of an initial R or Q wave > 40 milliseconds, and if present, is VT. If this criterion is not satisfied, then the presence of a notch on the descending limb of a negative onset and predominantly negative QRS gives the diagnosis of VT. If this is not present, then one should compare the voltage of the initial 40 milliseconds (V_i) with the voltage of the terminal 40 milliseconds (V_t) of the QRS complex. If $V_i/V_t \leq 1$, then it is VT. If none of these criteria are satisfied, then SVT is diagnosed.

3. **Therapy**

a. **General management.** The treatment of VT may involve DCC, discontinuation of offending proarrhythmic drugs, specific antiarrhythmic therapy with drugs, correction of electrolyte imbalances, implantable devices, ablation, revascularization, and surgery. The appropriate selection of the preceding therapies is aided by the assessment of the patient, an understanding of the etiology and mechanism of the VT, knowledge of any exacerbating medical conditions contributing to the VT, and the risk-to-benefit ratio of the available therapies.

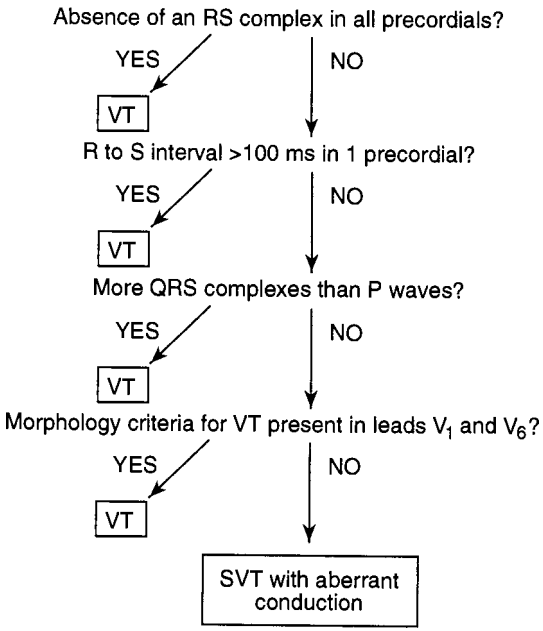

FIGURE 21.4 Brugada criteria for differentiating ventricular tachycardia from supraventricular tachycardia with aberrant intraventricular conduction. VT, ventricular tachycardia; SVT, supraventricular tachycardia.

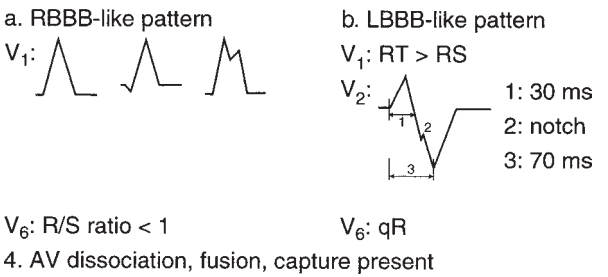
b. Priority of therapy. A patient who has no hemodynamic compromise can be treated medically, at least initially. As with most types of tachyarrhythmias, **the treatment of any unstable patient with VT is rapid DCC**. The treatment for pulseless VT is asynchronous DCC with a starting energy of 200 to 360 J. If the patient is conscious but has unstable vital signs or is extremely symptomatic, **synchronized DCC** is recommended. Current 2011 Advanced Cardiac Life Support (ACLS) guidelines (AHA) currently emphasize the delivery of high-quality cardiopulmonary resuscitation (CPR): effective chest compressions (100/min and compression depth of at least 2″) with minimal interruptions, rescue breaths given over 1 second with visible chest rise while avoiding hyperventilation (30:2 ratio before an advanced airway and 8 to 10 asynchronous breaths/min after airway is secured), and a **single** shock to attempt to defibrillate pulseless VT patients (as opposed to three-stacked shocks) followed by immediate continuation of CPR. (See Section **IV.F.3** for treatment of pulseless VT/VF patients.)

c. Acute medical therapy. Intravenous amiodarone, lidocaine, procainamide, β-blockers, and other oral agents may be given initially depending on the clinical scenario. Amiodarone is the agent of choice for resistant VT causing repeated episodes and also for pulseless VT/cardiac arrest. Amiodarone and lidocaine are the preferred agents in patients with LV dysfunction (left ventricular ejection fraction [LVEF] < 40%). Lidocaine is effective when VT is thought to be ischemic in nature. Procainamide is reasonable as the initial treatment in patients with stable monomorphic VT, as it more effectively provides early rate slowing and conversion than amiodarone. β-Blockers may be preferred for acute coronary syndrome, especially if not already being

1. QRS width > 0.14 s
2. Superior QRS axis
3. Morphology in precordial leads:



4. AV dissociation, fusion, capture present

FIGURE 21.5 Classic morphology criteria for ventricular tachycardia.

taken by the patient. Whenever possible, a **reversible cause for VT** should be sought. Elimination of **ischemia** and correction of **electrolyte abnormalities** are recommended. **Bradycardia** may cause frequent premature ventricular contractions or VT. Maneuvers and agents that increase heart rate should be employed for these bradycardias. **Hypotension** should be promptly corrected. Therapy for CHF should be optimized with the agents

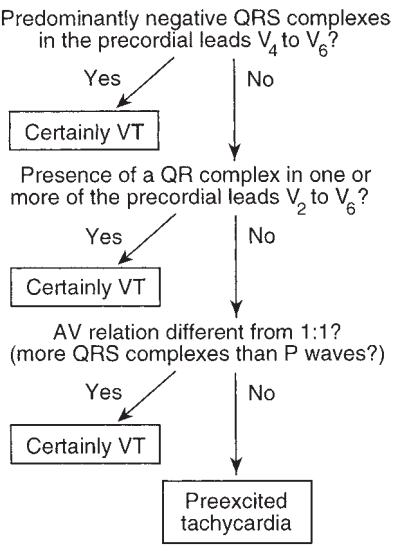


FIGURE 21.6 Brugada criteria for differentiating ventricular tachycardia from antidromic tachycardia over an accessory pathway. VT, ventricular tachycardia; AV, atrioventricular.

known to promote survival in this disorder. **Offending agents** should be stopped whenever possible, and **antidotes** should be administered in the case of overdosage and poisoning.

4. **Prevention and prophylactic treatment.** All antiarrhythmic agents to date, except β-blockers, have not been shown in randomized clinical trials to be effective as the primary management of patients with life-threatening ventricular arrhythmias or in the prevention of SCD. Since the Cardiac Arrhythmia Suppression Trial (CAST) data have become available, there has been a shift

away from the use of class I agents and toward the **use of class III agents and β-blockers for prophylactic maintenance therapy** of VT. The development of **curative catheter-based therapies and surgical procedures** has somewhat reduced the role of antiarrhythmics in the prevention of recurrence, especially for VT occurring in normal hearts, which has very high cure rates with catheter ablation **(see Section IV.A)**. However, antiarrhythmic drug therapy remains the first-line treatment for VT, particularly for patients with cardiomyopathy. The greatest impact on survival in sudden death has been made by the implantable **cardioverter–defibrillator (ICD)**. Data from the Multicenter Unsustained Tachycardia Trial (MUSTT) investigations have shown that **patients with CAD, an EF < 40% and NSVT who have inducible sustained VT on testing are at substantially increased risk** over those who do not have inducible VT.

a. Medical therapy

(1) Although drug therapy continues to have a role in the prevention of VT and sudden death, this role has become more limited as there has been no decrease in mortality with the use of antiarrhythmic drugs. The Electrophysiologic Studies Versus Electrocardiographic Monitoring (ESVEM) trial studied the efficacy of seven antiarrhythmics (imipramine, mexiletine, pirmenol, procainamide, propafenone, quinidine, and sotalol) in preventing the recurrence of sustained VT. Sotalol was seen to be the most effective, although even with sotalol the recurrence rate was disappointing. The European Myocardial Infarct Amiodarone Trial (EMIAT) and the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) investigations were designed to study the effectiveness of empiric amiodarone for the prevention of VT after MI. Although both of these trials showed a decrease in arrhythmic deaths, no survival benefit was recorded.

(2) Combination therapy. Drug therapy is becoming **an adjunct to ICD therapy** in this high-risk population. At present, fully half of those with ICDs remain on antiarrhythmic therapy. The rationale for this combined therapy includes preventing atrial tachyarrhythmias and reducing the frequency of VT and thus the frequency of ICD discharge.

(3) Calcium channel blockers are used primarily in the management of supraventricular tachyarrhythmia. However, some of the idiopathic monomorphic VTs, described in Section **IV.A** (the VTs originating in the right ventricular outflow tract [RVOT]), fascicular VT, and the VTs of digitalis toxicity are responsive to calcium channel blocking agents such as verapamil and diltiazem (due to the underlying mechanism of calcium-dependent triggered activity). RFA is potentially curative for idiopathic VTs and should be considered despite effective termination with calcium channel blockers.

(4) β-Blockers may be effective, particularly for outflow tract VT. Idiopathic left VT may respond to calcium channel blockers.

b. Percutaneous therapy

(1) ICDs. Two large trials comparing ICDs with amiodarone in high-risk patients with prior infarction, the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Antiarrhythmics Versus Implantable Defibrillator (AVID) trial, have been completed. High risk implies either an EF of 35% or less or the presence of inducible sustained VT at electrophysiologic study. Both trials showed a **decided advantage for ICDs**, with 30% to 50% reductions in mortality with ICDs. In fact, the AVID trial found no survival benefit from amiodarone, β-blockers, or any other antiarrhythmic agent. Newer ICDs often have antitachycardia pacing (ATP) capabilities, can recognize monomorphic ventricular

rhythms with rates < 200 beats/min, and can rapidly pace the ventricles to restore sinus rhythm, aborting the need for countershock (see Chapter 23). In the Primary Prevention Parameters Evaluation (PREPARE) study which evaluated the effects of ICD programming in a patient population receiving ICDs for primary prevention, using ATP as first-line therapy for fast VT (≥ 182 and < 250 beats/min), including a monitoring zone at 167 beats/min, and applying SVT versus VT discriminators for rates < 200 beats/min helped in reducing shocks without negatively affecting the mortality. Data from MADIT II have shown that in patients with a prior MI and an EF < 30%, the implantation of a defibrillator is associated with a significant improvement in survival.

(2) Catheter-based therapy. RFA may be effective for reducing the incidence of VT. The success rate depends on the type of VT, with the highest success rates (> 90%) in structurally normal hearts. VT associated with underlying cardiomyopathy has lower success rates with ablation, particularly those with arrhythmogenic RV cardiomyopathy and ischemic cardiomyopathy. However, catheter ablation still remains an effective and feasible approach, even for these types of VTs. Presently, catheter ablation of VT does not obviate the need for an ICD in a patient with an indication for one.

IV. DIAGNOSTIC EVALUATION OF A PATIENT WITH VT. Once the diagnosis of VT has been established and the patient has been acutely managed with either DCC or medical therapy, further management depends on the underlying cardiac pathology. In broad terms, the substrate can be divided into two categories: the structurally normal heart and the structurally abnormal heart. Various modalities are available to determine the cardiac structure and function, which include electrocardiography, cardiac catheterization, echocardiography, nuclear imaging, and magnetic resonance imaging.

A. VT in a structurally normal heart. About 10% of VT in the United States occurs in structurally normal hearts, the so-called idiopathic VT. These patients have no significant CAD, no family history of arrhythmia or sudden death, and normal surface ECGs. They can be focal VTs or reentry VTs. Focal VTs are a result of triggered activity, abnormal automaticity, or reentry within the Purkinje fibers.

1. Focal VT

a. Mechanism. Focal VTs most commonly arise from the RVOT and account for up to 70% of idiopathic VTs. They may be caused by cAMP-mediated EADs. Of particular importance in the diagnosis of a patient who presents with LBBB VT is to be cognizant of the possibility of arrhythmogenic right ventricular dysplasia (ARVD), which falls into the category of VT/PVCs in the structurally abnormal heart. The clinician should investigate for RV structural abnormalities (fatty infiltration), ask about a family history of ARVD, and review the electrogram for the presence of T-wave inversion across the right precordial leads, and/or epsilon waves (Fig. 21.10). A cardiac MRI or cardiac PET scan may also be useful to rule out the presence of cardiac sarcoidosis, which also would fall into the category of the structurally abnormal heart.

b. ECG. The surface ECG usually demonstrates an LBBB and inferior axis with very positive QRS voltage in inferior leads. Other locations of focal VTs may include the LV outflow tract, aortic cusps, pulmonary artery, mitral and tricuspid annuli, papillary muscles, and epicardium.

c. Treatment. In general focal VTs are benign, carrying a very low risk of SCD. Therefore, the treatment is predominantly guided by symptoms. Given the role of cAMP in inducing this form of VT, adenosine may be effective at acute termination. For longer term therapy in the symptomatic patient,

β-blockers are typically the first-line agents and can be effective in up to 50% of patients. The nondihydropyridine calcium channel blockers may also be effective in 25% to 50% of patients. Very effective medications are sotalol and amiodarone, with up to 90% success rate in eliminating symptoms, but potential side effects may limit their use. Patients who wish to potentially avoid lifelong medications or who are refractory to medical therapy can be considered for ablation, which has variable success rate depending on the location. RVOT VT ablation success rate may be as high as 90%. Ablation procedures, while generally safe, may be associated with infrequent but life-threatening complications, including cardiac perforation and tamponade.

2. **Fascicular VTs.** Fascicular VT involves reentry using the tissue of the LV septum as the antegrade limb and usually the posterior fascicle in the retrograde limb.
   a. **ECG.** This typically produced a right bundle branch block (RBBB) with left-axis deviation pattern. Less commonly, the QRS pattern is an RBBB with right-axis deviation (left anterior fascicular VT).
   b. **Treatment.** This subtype of VT may be verapamil-sensitive, but catheter ablation can be attempted in patients who want to avoid long-term medication or in whom medical therapy is ineffective.

B. VT/VF associated with channelopathies. Various cardiac ion channel disturbances can predispose to ventricular arrhythmias. Patients with these channelopathies have no overt structural heart disease. They are genetically heterogeneous and have variable penetrance. They include LQTS, short QT syndrome, Brugada syndrome, and catecholaminergic polymorphic VT.

1. **Long QT syndrome**
   a. **Pathology and presentation**

This channelopathy is characterized by prolonged cellular repolarization resulting in an increase of the QT interval. Clinical presentation includes syncope or sudden death as a result of torsade de pointes, and usually an autosomal dominant transmission pattern.

While at least 12 mutations have been identified, the most common subtypes of LQTS are LQT1, LQT2, and LQT3, which are characterized by mutations in the I_{Ks}, I_{Kr}, and I_{Na} channels, respectively. Interestingly, a minority of patients with the genetic mutation may actually have "normal" QT intervals. LQT1 and LQT2 mutations result in decreased outward potassium current, while LQT3 mutation results in increased inward sodium current, both of which result in prolonged cellular repolarization. The Jervell and Lange-Nielsen, a clinical syndrome with a constellation of a prolonged QT and sensorineural deafness, is transmitted in an autosomal recessive pattern, and thus far has been localized to the LQT1 or LQT5 mutations.

LQT1 patients typically have broad-based T waves and exercise-induced arrhythmias, especially during swimming. LQT2 syndrome is characterized by low-amplitude or notched T waves and auditory triggers such as sudden loud sounds like alarm clocks or strong emotion, and LQT3 is characterized by a long isoelectric ST segment and arrhythmias during sleep.

   b. **Treatment**

In patients with LQTS, risk stratification involves assessment of age, gender, clinical history, and possibly the QT interval and genetic mutation. While β-blockers have a variable efficacy depending on the type of LQT mutation, typically high doses of propranolol or nadolol are used to prevent clinical symptoms. For the LQT3 patients, there may be a role for flecainide given its effects on the sodium channel inhibition, but this is experimental and has not reached guideline recommendations yet. Patients should be advised against high-intensity sports and should be educated regarding avoidance of QT prolonging drugs. Patient with syncope, history of aborted

sudden death, or torsade de pointes despite β-blocker therapy should undergo ICD implantation. Certain high-risk subgroups such as patients with LQT3 in whom β-blockers may be less effective, patients with QTc > 550 milliseconds, or female LQT2 patients with QTc > 500 milliseconds may benefit from ICD implantation. Left cardiac sympathetic denervation can be used as an adjunctive therapy to reduce recurrence of arrhythmias.

2. **Short QT syndrome.** This syndrome is characterized by gain-of-function mutations in the I_{Ks}, I_{Kr}, and I_{K1} potassium channels or CACNA1 and CACNB2 L-type calcium channel mutations. ICD therapy is the primary treatment modality. However, particular attention needs to be given to the prevention of inappropriate shocks, as patients may have T-wave oversensing (tall T waves) and a high incidence of AF.
3. **Brugada syndrome.** Brugada syndrome is a condition associated with SCD in the setting of a structurally normal heart, characterized by an electrocardiographic pattern of RBBB and ST-segment elevation in leads V_1 to V_3 (Fig. 21.8). It is inherited in an autosomal dominant pattern with a male predominance. It is a genetically heterogeneous disease with many mutations linked to the gene *SCN5A*, which encodes for a cardiac sodium channel, leading to unopposed I_{to} potassium current in the RV epicardium. The diagnosis can be difficult because of the variable expression of the ECGs at baseline, changes in the ECG over time induced by a host of factors (temperature, heart rate, autonomic tone, and medications), and the wide range of clinical manifestations. The diagnosis should be considered in patients who have documented VF, self-terminating polymorphic VT, family members with ST-segment elevation, syncope, or family history of sudden death in the setting of the electrocardiographic findings noted previously. Currently, no medication has proved effective in preventing SCD in these patients, but quinidine, which blocks the I_{to} channel, may be used as an adjunctive therapy to reduce the likelihood of arrhythmias. ICDs are currently the only available treatment and are recommended in patients with previous cardiac arrest (class I), syncope with spontaneous ECG pattern (class IIa), and documented VT that has not resulted in cardiac arrest (class IIa). It is generally recommended to implant an ICD in **symptomatic** patients and clinically follow **asymptomatic** patients with an abnormal ECG only on pharmacologic provocation and no inducible ventricular arrhythmias.
4. **Catecholaminergic polymorphic VT.** This arrhythmia is more common in adolescents and children and may present with SCD or stress-induced syncope. While usually familial, it can also occur due to de novo mutations. Triggers often include emotional or physical stress, and the arrhythmia can be polymorphic, bidirectional, and less commonly, VF. Two culprit genes have been identified thus far: calsequestrin 2 (autosomal recessive pattern) and cardiac ryanodine receptor (autosomal dominant pattern). ICDs are indicated in patients with this syndrome and syncope and/or VT. β-Blockers can reduce the incidence of arrhythmias as well. Flecainide and sympathetic denervation have been used in some patients who are refractory to β-blocker therapy.

C. VT in the structurally abnormal heart

1. **Ischemic VT. Patients with ischemic VT may have acute ischemia leading to MI or a history of ischemic heart disease with scar.** Patients who have VF/VT within 48 hours of an acute MI have a relatively high inhospital and 30-day mortality compared with patients who do not have VF/VT.
   a. **Etiology and pathophysiology.** At the cellular level, ischemia may alter action potentials, prolong refractoriness of cells, and uncouple the cell-to-cell propagation of depolarization. The biochemical milieu in which the cells exist with respect to ion concentrations, acid–base balance, and so forth can be altered. Also, the myocardial damage as a result of infarction is structurally

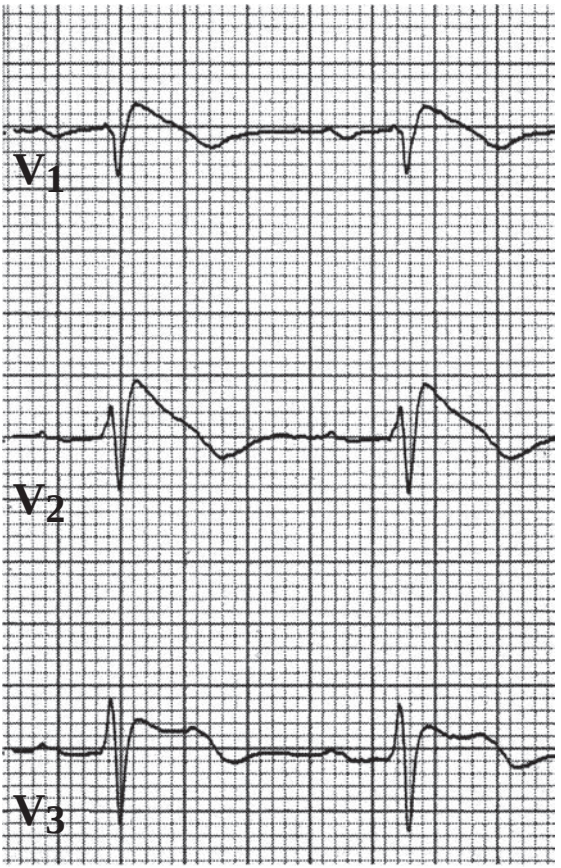

FIGURE 21.8 Leads V_1 through V_3, demonstrating Type 1 Brugada pattern.

heterogeneous. Therefore, scar tissue and healthy tissue are admixed in the region of the infarction. As described before, a reentrant circuit requires two functionally distinct pathways with unidirectional block in one pathway and slowed conduction down a second pathway. The changes associated with ischemia provide the anatomic substrate for reentry. The VT in the setting of ischemia tends to be **polymorphic**, while VT in the setting of established myocardial scar tends to be **monomorphic**. Ischemia has been shown to prolong the QT interval in some subjects, often with associated T-wave inversion. The **QT interval in ischemic-mediated polymorphic VT is not as prolonged** as that in torsade de pointes, another polymorphic VT. Ischemia is by far the **most common cause of polymorphic VT with normal QT interval**.

b. Predictors of VT. As might be expected, **larger infarcts with greater resultant impairment of LV systolic function** are more likely to be associated with VT. In fact, LV systolic function is the single most important predictor of sudden death due to arrhythmia. Similarly, the presence of an **open artery**

appears to reduce the occurrence of VT and other arrhythmias. Other proposed predictors include syncope, abnormal signal-averaged electrocardiogram (SAECG) result, NSVT, absence of heart rate variability, abnormal electrophysiologic study outcome, and T-wave alternans (TWA); however, currently, the LVEF remains the most accurate predictor of sudden death.

c. **Laboratory examination and diagnostic testing.** The various tests for risk stratification (electrophysiologic study, SAECG, heart rate variability, TWA, and so forth) have shown poor specificity and positive predictive value for VT **and thus should not be used alone to guide therapy but in combination with the rest of the clinical information**.

d. **Role for ICD.** In patients who present with a VF/VT arrest in the setting of an acute MI (within 24 to 48 hours of infarction), revascularization should be the primary initial treatment. Given the fact that acute ischemia is considered a "transient or potentially correctable cause" of VF/VT, and such patients were excluded from the AVID trial, based on currently guidelines, an ICD would be indicated 90 days after revascularization if the LVEF is ≤ 35% or after 40 days if no revascularization was performed, but treatment should be guided on a patient-to-patient basis. Of note, patients in the AVID registry who were excluded from the AVID trial due a "transient or potentially correctable cause" had a high mortality risk in follow-up. Of the 278 patients studied, 183 patients were determined to have ischemic causes. Of these, 161 were categorized as new myocardial infarction and 22 were categorized as transient ischemia. Other causes included electrolyte abnormalities, antiarrhythmic drug interaction, and "other (illicit drug use, sepsis, hypoxia, electrocution, drowning)". For patients who are post-MI and are deemed to be at high risk for SCD during the waiting period of 40 to 90 days, a wearable cardioverter–defibrillator (WCD) may provide protection against cardiac arrest, but no randomized clinical trials comparing WCDs with medical therapy in this post-MI period have been completed to date. Patients with late VT/VF (i.e., > 48 hours after acute MI) are deemed to be particularly high risk for recurrent VT/VF and therefore typically receive ICDs before hospital discharge. These patients are considered to meet secondary prevention indications for ICDs.

e. Accelerated idioventricular rhythm (Fig. 21.9) is a form of VT seen almost exclusively in ischemic heart disease, particularly during an MI and especially after reperfusion of an occluded territory. It may be seen with digitalis toxicity, but can also be present in healthy adults and children with no structural heart disease.

   (a) The electrocardiographic features include regular or slightly irregular ventricular rhythm, rate of 60 to 110 beats/min, a QRS morphology resembling that of PVCs, and, often, AV dissociation as well as fusion beats and capture beats.

   (b) **Pathophysiology.** The ectopic ventricular pacing focus competes with the SN and takes control of the ventricular rate when the sinus rate slows or when sinoatrial or AV block occurs. Enhanced automaticity is the likely underlying mechanism.

   (c) Accelerating the sinus rhythm with atropine or atrial pacing can be useful to suppress the accelerated idioventricular rhythm. **Therapy is rarely necessary, unless** the loss of AV synchrony results in hemodynamic compromise, a more rapid VT intervenes, the accelerated idioventricular rhythm falls on the T wave of the preceding beat (R on T phenomenon), the ventricular rate is rapid enough to produce symptoms, or VF occurs.

2. **Dilated cardiomyopathy (DCM).** Risk stratification is particularly difficult in patients with DCM as SAECG, microvolt TWA, and an electrophysiologic study are not reliable predictors in this population, and asymptomatic ventricular arrhythmias are common. The **Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation** (DEFINITE) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) have influenced the current guidelines for implanting ICDs in patients with DCM. ICDs are recommended for patients

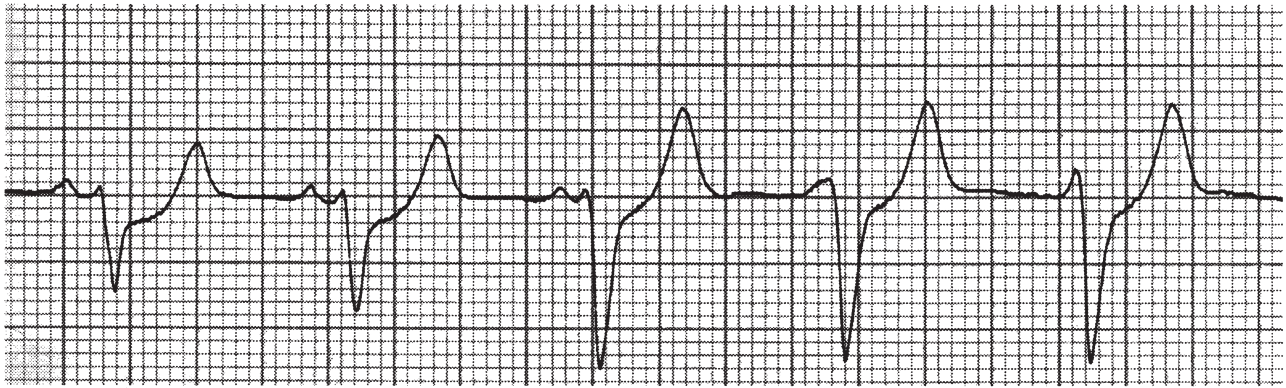

FIGURE 21.9 Accelerated idioventricular rhythm (beats 3 through 5), interspersed with normal sinus rhythm (beats 1 and 2), lead IV.

who manifest life-threatening arrhythmias or syncope and for primary prevention in patients who have an LVEF < 35% and are New York Heart Association (NYHA) classes I–III (less evidence exists for class I). All patients should be receiving chronic optimal medical therapy and have a life expectancy > 1 year. Bundle branch reentrant tachycardia occurs most commonly in patients with DCM for which electrophysiologic testing is helpful in diagnosing and guiding ablative treatment. Although ablation may be curative if bundle branch reentry is the mechanism, such patients should still be considered for ICD implantation.

3. **Hypertrophic cardiomyopathy.** Supraventricular tachyarrhythmia and AF are particularly poorly tolerated by these patients, as is ischemia, and may lead to VT. No prospective randomized trials regarding ICD therapy have been carried out to date in this patient population. Consequently, the precise risk stratification is debated. ICDs are recommended for patients who have sustained VT or VF, or both, and for primary prevention in patients who have either one of the preceding life-threatening arrhythmias or one or more of other major risk factors for SCD (nonsustained spontaneous VT, family history of premature SCD, unexplained syncope, LV thickness ≥ 30 mm, or abnormal exercise blood pressure). Again, all patients should be receiving chronic optimal medical therapy and have a life expectancy > 1 year. Electrophysiologic study may be helpful in stratifying risk for VT and sudden death. Patients at low risk for HCM include those with infrequent or brief episodes that are asymptomatic or mildly symptomatic. Although **amiodarone** may be beneficial in this population, an ICD is increasingly used in those considered to be at high risk.
4. **Muscular dystrophies**, particularly Duchenne's muscular dystrophy and myotonic dystrophy, have been associated with frequent defects in the conduction system. Heart block and bundle branch block as well as sudden death due to ventricular tachyarrhythmias are well-recognized complications of these muscular disorders.
5. **Congenital heart disease.** Structural abnormalities such as **repaired tetralogy of Fallot and mitral valve prolapse** have been associated with increased risk of VT and sudden death. In tetralogy of Fallot, the VT often originates in the RVOT, at the site of a previous repair. Risk of VT and sudden death in this population has been associated with QRS width (and rate of QRS width increase) as well as severity of pulmonary insufficiency. Mitral valve prolapse has been uncommonly linked to sudden death, although ventricular arrhythmias are not uncommon. **The prognosis with respect to VT is quite good in mitral valve prolapse**.
6. **Arrhythmogenic right ventricular cardiomyopathy** is a cardiomyopathy that begins in the right ventricle and often progresses to involve the left ventricle. It results in RV dilation with resultant poor contractile function. The RV muscle becomes increasingly replaced by adipose and fibrous tissues as the disease progresses. VT arising in the right ventricle is often an early manifestation of this disorder. The **VT is a reentrant type and has an LBBB morphology**, although in sinus rhythm there is often inversion of the T waves in the anterior precordial leads and a slurring of the terminal portion of the QRS complex, known as an epsilon wave (Fig. 21.10). These patients frequently have a positive SAECG for late potentials. The combination of the scarring and the late potentials provides the anatomic substrate for reentry. During electrophysiologic study, it may be possible to elicit VT of varying morphologies, due to the prolific scarring of the myocardium. The **risk of VT correlates with the extent of myocardial involvement**. Therapy with sotalol or high-dose amiodarone may be somewhat successful. Ablation via catheters is often successful, but only temporizing, as the generalized involvement tends to give rise to arrhythmias at a different locus later in the disease course. ICDs are often the only reliable therapy to prevent sudden

death in this disorder. Patients are advised against intense exercise, as this may promote the incidence and progression of arrhythmias.

7. Several inflammatory or infectious conditions have been associated with VT.
   a. Sarcoidosis is frequently cited as a cause of heart block and may also cause VT and VF. **Amiodarone** and **sotalol** are the most efficacious agents in this disorder, although an ICD may be necessary in addition to the drug therapy.
   b. Acute myocarditis has been associated with both polymorphic and monomorphic VTs. It may be intractable in giant cell myocarditis. **Antiarrhythmic therapy and anti-inflammatory therapy** are generally combined in the treatment of these patients.
   c. Chagas disease, caused by the parasite *Trypanosoma cruzi*, is a well-known cause of cardiomyopathy, particularly in South and Central America. VT and other arrhythmias due to conduction system involvement are common complications. Therapy involves antiparasitic treatment, standard therapy for CHF, antiarrhythmics, and pacemaker or ICD implantation, as appropriate. Some patients require catheter ablation of refractory VT, which sometimes must be performed epicardially.
8. **Coronary anomalies.** Anomalous aortic origin of the coronary artery is recognized as a cause of sudden death and/or exercise-induced death in young individuals. In an autopsy study of over 200 patients conducted by the Armed Forces Institute of Pathology, the most common coronary anomalies included the right coronary artery and left main coronary artery arising from the left sinus, the left main and right coronary arteries arising from the right sinus, single coronary artery from the aorta, and the left main or left anterior descending artery arising from the pulmonary artery. Patients whose coronary arteries take an interarterial course (between the pulmonary artery and the aorta) may develop exercise-induced ischemia and/or sudden death. Surgical revascularization in patients with symptomatic coronary anomalies has been well described. Surgical treatment for patients with high-risk coronary anomalies who are asymptomatic is controversial.

D. Drug-induced VT. Drugs are a well-known cause of VT, both polymorphic and monomorphic VTs. This is particularly true in ischemic or infarcted hearts. Phenothiazines, tricyclic antidepressants, digitalis, epinephrine, cocaine, nicotine,

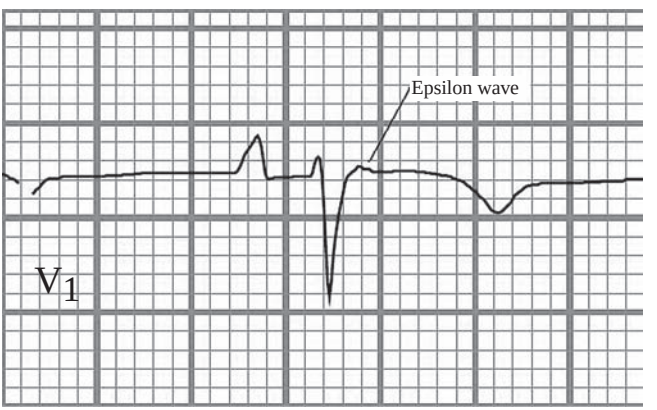

FIGURE 21.10 Epsilon wave in a patient with arrhythmogenic right ventricular dysplasia.

alcohol, and glue (inhaled) are some of the wide variety of drugs that have been implicated in the development of monomorphic VT. The CAST and other trials of the late 1980s showed an increase in mortality resulting from the use of class I antiarrhythmic agents employed to suppress asymptomatic ventricular ectopy after MI. NSVT and depressed LV function remain risk factors for sudden death, and the agents studied in CAST did decrease the occurrence of ventricular ectopy; however, it is believed that these drugs (flecainide, encainide, and moricizine) generated VT, causing sudden death in recipients. These agents all have in common their sodium channel blocking activities. Other drugs in this class, including procainamide, quinidine, disopyramide, lidocaine, tocainide, and mexiletine, have all been shown either experimentally or clinically to be associated with increased mortality compared with controls in the periinfarction period. The results of CAST caused a major shift away from the sodium channel blocking agents (class I antiarrhythmics) in the periinfarction period.

1. The generation of torsade de pointes due to effects on the QT interval is discussed in Section **IV.D.2**.
2. Digitalis toxicity can propagate DADs, which generate action potentials, leading to VT. The VT of digitalis toxicity is typically monomorphic and often responds to calcium channel blockers. Rarely, digitalis toxicity manifests as a bidirectional VT, meaning that it has a regular rhythm with an axis that alternates from −60 to −90° to +120 to +130°, with a ventricular rate from 140 to 200 beats/min. Because digitalis toxicity may have a narrow QRS complex and may respond to calcium channel blockers, it may be confused with supraventricular tachyarrhythmia. This type of VT is best managed by removing the offending agent, digoxin, with its binding antibody. The treatment for digitalis toxicity is the same in the face of bidirectional VT.
   a. Torsade de pointes is a type of polymorphic VT associated with delayed myocardial repolarization, most often manifested as a prolonged QT interval. Although the duration of torsade de pointes is typically brief (< 20 seconds), it can be sustained and can degenerate into VF. It generally has an irregular ventricular rate (> 200 beats/min) and displays a polymorphic structure with an undulating appearance. The QRS complexes appear to twist around an isoelectric axis. Characteristics that distinguish torsade de pointes from other forms of VT include (1) prolonged QT interval, (2) initiation with a short–long–short sequence, and (3) typical "twisting of the points" appearance of the VT.
      (1) **Etiology.** QT prolongation can be congenital or acquired.
         (a) The **congenital** forms are seen in the LQTS, discussed in Chapter 23.
         (b) The **acquired forms are most often drug induced**, although polymorphic VT with a prolonged QT can be caused by electrolyte abnormalities, hypothyroidism, cerebrovascular events, MI or ischemia, starvation diets, organophosphate poisoning, myocarditis, severe CHF, and mitral valve prolapse.

      The **most commonly implicated drugs have been the class IA drugs**, although less frequent occurrences have been reported with all subclasses of class I antiarrhythmics. The class III drugs, such as sotalol, dofetilide, and, less commonly, amiodarone, have been implicated. The incidence of torsade de pointes with sotalol is in the range of 2% to 5% and with dofetilide it is < 1%. Ibutilide is an antiarrhythmic agent for supraventricular tachyarrhythmias that is associated with an incidence of torsade de pointes at least as high as that of sotalol. Other drugs implicated include the phenothiazines, haloperidol, and the tricyclic antidepressants. Antibiotics, including erythromycin and other macrolides, as well as trimethoprim–sulfamethoxazole combinations, have been implicated. The macrolides are particularly prone to cause torsade de pointes when combined with certain antihistamines such

as astemizole and terfenadine. These antihistamines have also been found to cause torsade de pointes when combined with certain azole antifungal agents such as ketoconazole. Ionic contrast and promotility agents such as cisapride have also been associated with torsade de pointes. Medications associated with increasing QT interval are listed on the following website: www.torsades.org. It is maintained by the University of Arizona Center for Education and Research on Therapeutics.

Bradycardia can promote torsade de pointes in patients with prolonged QT intervals, although it is not clear if bradycardia by itself predisposes to torsade de pointes. Specifically, pause-dependent VT occurs in the setting of bradycardia and a prolonged QT interval. Usually a long RR interval followed by a short RR interval followed by another long RR interval initiates the VT.

Electrolyte disorders. **Hypokalemia** is the electrolyte disorder most reliably linked to torsade de pointes. **Hypomagnesemia** has been proposed as a logical cause, as the administration of magnesium frequently terminates torsade de pointes. However, there is scant evidence to confirm this. Likewise, although **hypocalcemia** is associated with prolongation of the QT interval, there are only rare reports of torsade de pointes associated with hypocalcemia.

Short coupled VT. Polymorphic VT is initiated < 400 milliseconds following the preceding QRS complex.

R-on-T phenomenon occurs when a defibrillation or pacing current or spike is delivered simultaneously with occurrence of the electrocardiographic T wave resulting in polymorphic VT.

A variety of **cerebrovascular events** have been associated with torsade de pointes, most notably subarachnoid hemorrhage. The prolongation of the QT interval sometimes seen with intracranial bleeding is usually transient, resolving within weeks.

(2) Therapy. Acute management is aimed at terminating the arrhythmia.

(a) If torsade de pointes is sustained or associated with hemodynamic compromise, prompt DCC should be carried out. Starting voltages are generally 50 to 100 J and can be advanced to 360 J if necessary.

(b) Correction of hypokalemia, hypomagnesemia, and hypocalcemia should be undertaken promptly. Magnesium can be given in a bolus form at a dose of 1 to 2 g, with a total dose of 2 to 4 g given over 10 to 15 minutes. This successfully terminates torsade de pointes within 5 minutes in up to 75% of patients and within 15 minutes in virtually all patients.

(c) Bradycardia can be corrected with either isoproterenol infusion or temporary transvenous pacing. Pacing may be preferable when readily available, due to the potential complications of isoproterenol therapy (worsened ischemia and hypertension). Offending agents should be discontinued.

E. Miscellaneous

Commotio cordis. Commotio cordis is the sudden ventricular arrhythmia occurring as a result of a blunt, nonpenetrating impact to the precordial region, which is most commonly observed in young healthy persons during participation in sports. The blow likely falls within a small 10- to 30-millisecond window of ventricular vulnerability just prior to the peak of the T wave that results in polymorphic VT and sudden death. A 2002 case series of 128 individuals showed that only 16% of patients survived an episode of commotio cordis, with most returning to a baseline level of function. Prompt CPR/defibrillation was the only identifiable factor associated with a favorable outcome.

F. Ventricular fibrillation

1. VF is a **chaotic ventricular rhythm that reflects no organized electrical activity and hence no cardiac output** from the ventricle. It is devoid of the distinct elements that makeup the usual electrical complex of ventricular activity. It is a **rapidly fatal rhythm, and if resuscitation is not begun within 5 to 7 minutes, death is virtually certain**. VF is often preceded by VT. Virtually all of the risk factors and conditions discussed for VT are applicable to VF. It may arise without any inciting cardiac rhythm or event.
2. **Course of disease.** Of patients who experience an out-of-hospital cardiac arrest, 75% have VF as their initial cardiac rhythm. Of those successfully resuscitated, 75% have significant CAD and 20% to 30% have a transmural infarction. Patients without an ischemic etiology have an increased risk of further episodes of sudden death, whereas those who have an MI associated with sudden death have a 1-year recurrence rate of 2%. Anterior MI complicated by VF represents a subgroup at high risk for recurrence of sudden death. Predictors of SCD include evidence of ischemia, decreased LV systolic function, 10 or more PVCs per hour on telemetry, inducible or spontaneous VT, hypertension and LV hypertrophy, smoking, male sex, obesity, elevated cholesterol, advanced age, and excessive alcohol use.
3. **Therapy.** As noted previously, VF is a rapidly fatal rhythm, which virtually never terminates spontaneously. CPR must be initiated promptly and rapid, asynchronous DCC performed as soon as possible. A **single** shock of 200 to 360 J (biphasic devices, 200 J; monophasic devices, 360 J) should be given initially followed by immediate resumption of CPR for 2 minutes before checking for a pulse. If VF/pulseless VT persists, an immediate **second** shock (biphasic devices, ≥ 200 J; monophasic devices, 360 J) should be given followed by a vasopressor (1 mg of epinephrine every 3 to 5 minutes; single dose of 40 units of vasopressin may replace first or second dose of epinephrine). If VF/pulseless VT persists after two or three shocks, CPR, and a vasopressor, administration of an antiarrhythmic should be considered (amiodarone is preferred and lidocaine as an alternative). The emphasis should be on performing high-quality CPR with interruptions in chest compressions **only** for ventilation (until an advanced airway is established), rhythm checks (pulse checks only if an organized rhythm is observed), and shocks.

   See Chapter 23 for a discussion about the long-term treatment of survivors of VF.

G. Ventricular premature depolarizations and nonsustained ventricular tachycardia.

1. **VPDs** are common in patients with both structurally normal and structurally abnormal hearts. They are usually not hemodynamically significant, except in patients with depressed EF or in patients with frequent VPDs and/or bradycardia. Whether or not VPDs increase risk of subsequent cardiovascular events depends on the study. In the ARIC study, after controlling for cardiovascular risk factors, patients with a single VPD on a 2-minute Holter had over a two-fold incidence of dying of CAD over a 10-year follow-up period compared with patients who had no VPDs. However, in the Baltimore Longitudinal Study on Aging which evaluated ambulatory ECGs on apparently healthy subjects ≥ 60 years of age, VPDs on ambulatory ECG monitoring did not predict the development of coronary events. One main difference between the ARIC study and the Baltimore Longitudinal Study was that in the latter, inclusion criteria were more strict, requiring a normal exercise stress test, and therefore, likely had less patients with subclinical CAD.

   Although patients post-MI with VPDs have a higher mortality than patients post-MI without VPDs, suppression of VPDs with antiarrhythmic medication is associated with increased mortality. For patients with symptomatic VPDs, β-blockers or calcium channel blockers should be the first-line agent. If this fails and the patient has no structural heart disease, class IC

agents may be effective; however, potential risks and benefits of the antiarrhythmic drug should be explained to the patient. Sotalol has been shown to reduce the frequency of VPDs by 70% to 80%. In CAMIAT, amiodarone reduced VPDs and arrhythmic deaths, but did not reduce overall mortality. **A very high burden of VPDs (> 20,000/d) may be associated with reduced** EF**, although it may be difficult to determine if the VPDs caused the cardiomyopathy or vice versa**. However, in some patients with a high burden of VPDs and idiopathic DCM, treating the VPDs either with medication or with catheter ablation may improve the LVEF. Ablation can be an alternative approach to treatment in patients with very symptomatic VPDs refractory to medical therapy and/or patients with reduced EF thought to be a result of the VPDs.

2. **NSVT** is defined as VT of duration < 30 seconds. It can occur in up to 4% of healthy adults and increases in frequency as people age, and NSVT during exercise is not associated with a poor cardiovascular prognosis. The approach to NSVT is based on the cardiac substrate. However, patients with frequent polymorphic NSVT should undergo an evaluation for LQTS and catecholaminergic VT (Sections **IV.B.1** and **IV.B.4**, respectively). One should also be mindful of repetitive monomorphic NSVT that may be of LBBB morphology in patients who have a family history of arrhythmias or sudden death, which may suggest ARVD. Monomorphic NSVT may also be a part of the spectrum of the outflow tract VTs (Section **IV.A.1**).
   a. In patients in whom structural heart disease has been excluded, NSVT does not carry prognostic significance. Treatment should therefore only be guided by symptoms. A similar approach to NSVT with regard to medication choices is used as with symptomatic VPDs (Section **IV.G.1.**)
   b. Structural heart disease. In patients with MI, NSVT within the first 24 to 48 hours has little prognostic significance. However, NSVT > 48 hours after acute MI may increase the risk of sudden death by almost twofold, and the risk is even higher in patients with reduced LV function. **Patients with CAD, an EF < 40%, and NSVT who have inducible sustained VT on testing are at substantially increased risk** over those who do not have inducible VT. In patients with HCM, NSVT on Holter monitoring is one of the major risk factors of SCD. Patients with mitral valve prolapse and aortic stenosis who have NSVT are not at increased risk for SCD compared with those without NSVT. In patients with nonischemic DCM, NSVT is not an independent predictor of sudden death.

CHAPTER 22

Santosh S. Oommen

Bradyarrhythmias, Atrioventricular Block, Asystole, and Pulseless Electrical Activity

I. INTRODUCTION.

Bradyarrhythmias and **conduction blocks** are common electrocardiographic findings. Many of these arrhythmias are asymptomatic and do not require specific therapy, whereas others can be life threatening, requiring rapid intervention. **Myocardial ischemia** is an important cause of acute and potentially dangerous bradyarrhythmia.

II. ANATOMY

A. Sinoatrial node.

The sinus beat originates in the **sinoatrial (SA) node**, a focus of automatic cells near the junction of the superior vena cava and right atrium.

1. The blood supply to the SA node is from the **sinus node artery**, which arises from the proximal **right coronary artery** in 55% of the population (Fig. 22.1) and from the **circumflex artery** in 35%. The SA node receives a dual supply of blood from both the right coronary artery and the circumflex artery in 10% of the population.
2. The automaticity of the SA node is affected by both the parasympathetic and sympathetic nervous systems. If the SA node fails to generate an impulse, other foci in the atrium, atrioventricular (AV) node, or ventricle can act as "backup" pacemaker sites.

B. AV node.

The AV node is located in the anteromedial portion of the right atrium just anterior to the coronary sinus.

1. The impulse generated by the SA node progresses through the atrium to the AV node. The AV node is also innervated by both the parasympathetic and sympathetic nervous systems.
2. The AV node receives its blood supply from the AV node artery, which arises from the posterior descending artery in 80% of the population (Fig. 22.1), from the circumflex artery in 10%, and from both arteries in 10%.
3. Collateral blood supply from the left anterior descending artery makes the AV node somewhat less prone to ischemic damage than the SA node.

C. His bundle and bundle branches

1. After a delay of < 200 milliseconds in the AV node, the electrical impulse is propagated down the His bundle to the right and left bundle branches. The **left bundle branch splits further into anterior and posterior fascicles**. The autonomic nervous system does not have a major effect on conduction below the AV node.
2. The **His bundle and right bundle branch** receive their blood supply from the AV nodal artery and from septal penetrating branches of the left anterior descending artery. The anterior fascicle of the **left bundle branch** receives blood from the septal perforating branches of the left anterior descending

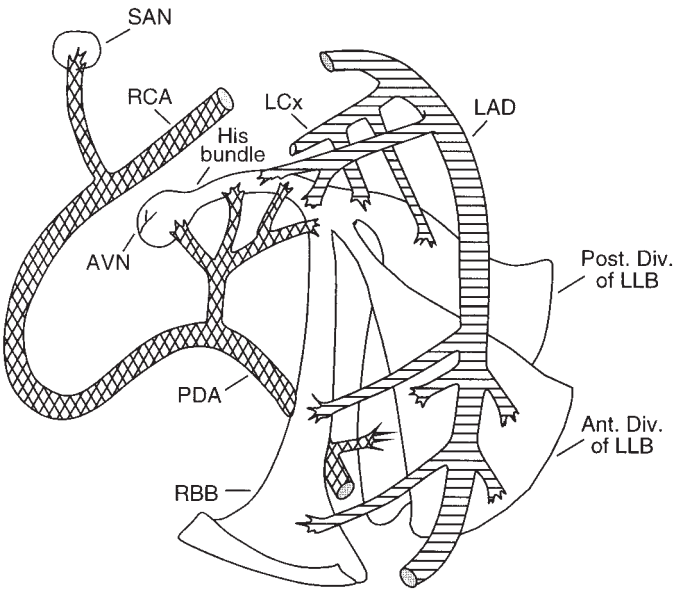

FIGURE 22.1 Diagrammatic representation of the conduction system and its blood supply. SAN, sinoatrial node; RCA, right coronary artery; AVN, atrioventricular node; PDA, patent ductus arteriosus; RBB, right bundle branch; LCx, left circumflex artery; LAD, left anterior descending; LLB, left lateral branch.

artery. The posterior fascicle has a dual blood supply: from the septal perforating branches of the left anterior descending artery and branches of the posterior descending artery.

III. SINUS NODE DYSFUNCTION. Sinus node dysfunction encompasses any dysfunction of the sinus node and includes **inappropriate sinus bradycardia**, SA **exit block**, SA **arrest, and tachycardia–bradycardia syndrome**.

A. Clinical presentation. There is a wide range of presentations, and some patients' disease may be asymptomatic.

1. Syncope and **presyncope** are the most dramatic presenting symptoms. **Fatigue, angina, and shortness of breath** are more subtle consequences of sinus node dysfunction.
2. In the tachycardia–bradycardia syndrome, the primary complaint may be palpitation. Documentation of the arrhythmia may be difficult because of the sporadic and fleeting nature of the problem.

B. Etiology. The intrinsic and extrinsic causes of sinus node dysfunction are listed in Table 22.1. **Idiopathic degenerative disease** is the most common cause of intrinsic sinus node dysfunction, and the incidence increases with age. **Acute coronary syndromes** are a common cause of bradyarrhythmias, occurring in 25% to 30% of patients with myocardial infarction (MI) (Table 22.2).

C. Electrocardiographic findings

1. Inappropriate sinus bradycardia, also known as "chronotropic incompetence," is defined as a sinus rate of < 60 beats/min that does not increase appropriately

TABLE 22.1 Etiologies of Sinus Node Dysfunction

Intrinsic causes
Idiopathic degenerative disease
Coronary artery disease
Cardiomyopathy
Hypertension
Infiltrative disorders (amyloidosis, hemochromatosis, and tumors)
Collagen vascular disease (scleroderma and systemic lupus erythematosus)
Inflammatory processes (myocarditis and pericarditis)
Surgical trauma (valve surgery and transplantation)
Musculoskeletal disorders (myotonic dystrophy and Friedreich's ataxia)
Congenital heart disease (postoperative or in the absence of surgical correction)
Extrinsic causes
Drug effects
β-Blocking agents
Calcium channel blocking agents
Digoxin
Sympatholytic antihypertensives (clonidine, methyldopa, and reserpine)
Antiarrhythmic drugs
Type IA (quinidine, procainamide, and disopyramide)
Type IC (flecainide and propafenone)
Type III (sotalol and amiodarone)
Others (lithium, cimetidine, amitriptyline, and phenytoin)
Autonomic influences
Excessive vagal tone
Carotid sinus syndrome
Vasovagal syncope
Well-trained athletes (normal variant and not dysfunction)
Electrolyte abnormalities
Hyperkalemia
Hypercarbia
Endocrine disorders—hypothyroidism
Increased intracranial pressure
Hypothermia
Sepsis

TABLE 22.2 Incidence of Bradyarrhythmia in the Setting of Acute Myocardial Infarction

Rhythm	Incidence (%)
Sinus bradycardia	25
Junctional escape rhythm	20
Idioventricular escape rhythm	15
First-degree AV block	15
Second-degree, Mobitz type I AV block	12
Second-degree, Mobitz type II AV block	4
Third-degree AV block	15
Right bundle branch block	7
Left bundle branch block	5
Left anterior fascicular block	8
Left posterior fascicular block	0.5

AV, atrioventricular.

with exercise. Inappropriate sinus bradycardia must be differentiated from a low resting heart rate, which may be normal in athletes and sleeping individuals.

2. Sinus arrest, or sinus pause, occurs when the sinus node fails to depolarize on time. Pauses of < 3 seconds may be seen on Holter monitoring in up to 11% of normal adults (especially athletes) and are not a cause for concern. However, **pauses lasting longer than 3 seconds are generally considered abnormal and are suggestive of underlying pathology**, especially if the patient is awake when they occur.
3. SA exit block, although similar to sinus arrest on the electrocardiographic tracing, may be distinguished by the fact that the **duration of the pause is a multiple of the sinus PP** interval. High-grade SA exit block cannot be differentiated from prolonged sinus arrest and is treated in the same manner.
4. Tachycardia–bradycardia syndrome, also referred to as "sick sinus syndrome," is characterized by episodes of sinus or junctional bradycardia interspersed with an atrial tachycardia, usually paroxysmal atrial fibrillation.

D. Diagnostic testing. Invasive testing is used when noninvasive methods have failed to yield a diagnosis and sinus node dysfunction is still strongly suspected.

1. **Noninvasive testing**
   a. **Electrocardiogram (ECG).** In evaluating sinus node dysfunction, the initial workup should include a 12-lead ECG, followed by a 24-hour to 48-hour ambulatory ECG monitoring, if necessary. Use of a diary during the recording period can help correlate symptoms with the cardiac rhythm. For less frequent events, a loop recorder or an event recorder may be used to assess symptoms over a 2-week to 4-week period. Stress testing can help document the severity of chronotropic incompetence.
   b. Autonomic testing includes physical maneuvers, such as carotid sinus massage and tilt table testing, as well as pharmacologic interventions to test the autonomic reflexes.
      (1) Carotid sinus massage distinguishes intrinsic sinus pause/sinus arrest from a pause due to **carotid sinus hypersensitivity**, which is a 3-second

or longer pause and/or a ≥ 50 mm Hg or greater drop in blood pressure that occurs with massage of the carotid sinus (firm pressure applied to one carotid sinus at a time for 5 seconds). **Carotid sinus massage should not normally precipitate sinus pause/sinus arrest**, although it will decrease the rate of depolarization of the SA node and slow conduction in the AV node.

(2) Tilt table testing may help differentiate between syncope caused by sinus node dysfunction and that due to autonomic dysfunction. **Bradycardic episodes precipitated by tilt table testing are usually caused by autonomic dysfunction and not by sinus node dysfunction**.

(3) Pharmacologic testing may be used to differentiate between sinus node dysfunction and autonomic dysfunction. Total autonomic blockade is achieved after administration of atropine 0.04 mg/kg and propranolol 0.2 mg/kg. The resulting intrinsic heart rate represents the sinus node rate, devoid of autonomic influences. Assuming that the normal intrinsic heart rate (in beats/min) is defined by the formula

$$\text{Intrinsic heart rate} = 118.1 - (0.57 \times \text{age})$$

then an intrinsic heart rate lower than predicted using this formula is consistent with sinus node dysfunction; an intrinsic heart rate close to the predicted rate in a patient with a clinical presentation of sinus node dysfunction is suggestive of an autonomic dysfunction as a cause of the bradyarrhythmia.

2. Invasive testing. The two most common tests use indirect measurements of SA node function. Direct measurement of SA node function is laborious and rarely performed.

a. Sinus node recovery time (SNRT) is the time it takes the SA node to recover following paced overdrive suppression of the node.

(1) A delay of longer than 1,400 milliseconds is considered abnormal. This measurement may be corrected by subtracting the intrinsic sinus cycle length (in milliseconds) from the recovery time. **A corrected SNRT > 550 milliseconds is suggestive of sinus node dysfunction**.

(2) The limitations of this test are as follows:

(a) It is an indirect measurement of SA node function and reflects both sinoatrial node conduction time(SACT) and automaticity.

(b) It may be falsely shortened by an SA node entrance block during atrial pacing (due to failure of the paced impulse to reset the sinus node) or falsely prolonged by an SA node exit block (the sinus node is normal but the impulse cannot leave the node), which affects its specificity.

(c) The SNRT is not prolonged in all patients with sinus node dysfunction, which affects its sensitivity.

b. Sinoatrial node conduction time

(1) The steady-state atrial rate is determined (A_1–A_1 interval or the time between P waves). Then premature atrial **extra stimuli** (A_2) are introduced by pacing high in the right atrium, starting in late diastole at progressively shorter intervals until atrial refractoriness is found (i.e., A_2 does not result in a P wave). The duration before the next spontaneous atrial impulse (A_3) is measured and the baseline rate is subtracted.

$$\text{SACT} = (A_2 - A_3 \text{ interval}) - (A_1 - A_1 \text{ interval})$$

(2) The test assumes that SA node automaticity is not affected by pacing, that conduction time into the node is equal to conduction time out of the node, and that there is no shift in the principal pacemaker site.

E. Therapy. Treatment for symptomatic sinus node dysfunction may be pharmacologic, pacing, or a combination of both.

1. Indications for pacing in sinus node dysfunction are determined by symptoms (e.g., correlation with a documented arrhythmia; Table 22.3). Another common indication is when drug therapy that causes sinus node dysfunction cannot be stopped or changed.
2. Medications that suppress sinus node automaticity should be stopped if possible. If this is not possible, it may be necessary to place a temporary or permanent pacemaker (Table 22.3).
3. For patients with **tachycardia–bradycardia syndrome**, a pacemaker is often placed for management of the bradyarrhythmia, and antiarrhythmic drugs are added for treatment of the tachycardia episodes.
4. Acute treatment for patients with **symptomatic sinus node dysfunction** includes the following:
   (a) Atropine (0.04 mg/kg intravenous bolus)
   (b) Temporary pacing for patients whose conditions fail to respond to drug therapy
   (c) Isoproterenol (starting at 1 μg/min intravenously), which may be used as a bridge to pacemaker placement. Isoproterenol is not indicated in most patients with cardiac arrest

IV. AV CONDUCTION DISTURBANCES. These disturbances are classified as first-degree, second-degree, or third-degree block, depending on the severity of the conduction abnormality.

A. Classification

1. First-degree AV block is characterized by the prolongation of the PR interval beyond 200 milliseconds. This finding may occur as a normal variant in 0.5% of asymptomatic young adults without overt heart disease. In older individuals, it is most often caused by idiopathic degenerative disease of the conducting system.
2. **Second-degree** AV **block**
   a. Second-degree AV block is characterized by **a failure of one or more, but not all, atrial impulses to conduct to the ventricles**. The block may be at any level of the AV conduction system.
   b. When more than one atrial impulse is present for each ventricular complex, the rhythm may be described as a ratio of the number of atrial impulses to the number of ventricular complexes (for three P waves preceding each QRS complex, 3:1 second-degree AV block is present).
      (1) Lesser degrees of AV block (i.e., 4:3 or 3:2) with a prolonging PR interval prior to a nonconducted atrial impulse are described as **Mobitz type I AV block** (also known as Wenckebach block).
         (a) The conducted impulse of a **Mobitz type I block** will generally be narrow, and the site of block is often in the AV node above the His bundle.
         (b) A Mobitz type I block with a bundle branch block is still likely to be above the His bundle, but a His bundle ECG is needed to confirm the level of block.
      (2) High-grade AV block (3:1, 4:1, or greater) is typically described as **Mobitz type II AV block**. The conducted impulses will generally be preceded by constant PR intervals and have a wide QRS morphology (right bundle branch block [RBBB] or left bundle branch block [LBBB] pattern). The site of block is often below the AV node. A **Mobitz type II block** is usually intra-Hisian or infra-Hisian and has a greater propensity for progressing to third-degree AV block.
      (3) Pure 2:1 conduction patterns cannot be reliably classified as Mobitz type I or type II, and if diagnostic maneuvers (such as exercise) are not able to elucidate one type of second-degree block versus the other, an electrophysiology study may be warranted.

TABLE 22.3 Indications for Permanent Pacing

Indication	Class I	Class II	Class III
SND	1. SND documented in association with symptomatic bradycardia and due to factors that are irreversible or due to essential drug therapy 2. Symptomatic chronotropic incompetence	IIa. No clear association between SND with heart rate < 40 beats/min and symptoms can be documented IIb. In minimally symptomatic patients, chronic heart rate < 40 beats/min while awake	1. SND with marked sinus bradycardia or pauses but no associated symptoms including that due to long-term drug therapy 2. SND in patients with symptoms suggestive of bradycardia that are clearly documented as *not* associated with a slow heart rate 3. SND with symptomatic bradycardia due to nonessential drug therapy
Acquired AV block	1. Third-degree AV block at any anatomic level, associated with any one of the following conditions: a. Bradycardia with symptoms presumed to be due to AV block b. Arrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia c. Documented periods of asystole ≥ 3.0 s, or an escape rhythm below the AV node, or any escape rate < 40 beats/min in awake, symptom-free individuals in sinus rhythm d. Documented pauses > 5 s in awake, symptom-free patients who are in atrial fibrillation	IIa. 1. Asymptomatic third-degree AV block at any anatomic site with average awake ventricular rates ≥ 40 beats/min 2. Asymptomatic type II second-degree AV block. Of note, when type II second-degree AV block occurs with a wide QRS, including isolated right bundle branch block, pacing becomes a class I recommendation 3. Asymptomatic type I second-degree AV block at intra-His or infra-His levels found incidentally at EP study performed for other indications	1. Asymptomatic one-degree AV block 2. Asymptomatic type I second-degree AV block at the supra-His (AV node) level or not known to be intra-Hisian or infra-Hisian 3. AV block expected to resolve and unlikely to recur (e.g., drug toxicity and Lyme disease)

Indication	Class I	Class II	Class III
	e. After catheter ablation of the AV junction f. Postoperative AV block that is not expected to resolve g. Neuromuscular diseases with AV block such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's dystrophy (limb girdle), and peroneal muscular dystrophy h. Permanent pacemaker implantation is indicated for asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 beats/min or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node. i. Permanent pacemaker implantation is indicated for second-degree or third-degree AV block during exercise in the absence of myocardial ischemia 2. Second-degree AV block regardless of type or site of block, with associated symptomatic bradycardia	4. First-degree AV block with symptoms suggestive of pacemaker syndrome and documented alleviation of symptoms with temporary AV pacing	
Post–myocardial infarction	1. Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree AV block within or below the His-Purkinje system after acute myocardial infarction	IIa. None IIb. 1. Persistent second-degree or third-degree AV block at the AV node level, even in the absence of symptoms	1. Transient AV block without intraventricular conduction defect 2. Transient AV block in the presence of isolated left anterior fascicular block

(Continued)

TABLE 22.3 Indications for Permanent Pacing (*Continued*)

Indication	Class I	Class II	Class III
	2. Transient advanced (second-degree or third-degree) infranodal AV block and associated bundle branch block. If the site of block is uncertain, an EP study may be necessary 3. Persistent and symptomatic second-degree or third-degree AV block		3. Acquired left anterior fascicular block in the absence of AV block 4. Persistent first-degree AV block in the presence of bundle branch block that is old or age indeterminate
Chronic bifascicular and trifascicular blocks	1. Intermittent third-degree AV block 2. Type II second-degree AV block 3. Alternating bundle branch block	IIa. 1. Syncope not proved to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia 2. HV interval > 100 milliseconds 3. Pacing-induced block below the His that is not physiologic	1. Fascicular block without AV block or symptoms 2. Fascicular block with first-degree AV block without symptoms
Carotid sinus hypersensitivity (carotid sinus irritability) and neurally mediated syncope	1. Recurrent syncope caused by carotid sinus stimulation; minimal carotid sinus pressure induces ventricular asystole of > 3 s duration in the absence of any medication that depresses the sinus node or AV conduction	IIb. None IIa. 1. Recurrent syncope without clear, provocative events and with a hypersensitive cardioinhibitory response 2. Syncope of unexplained origin when major abnormalities of sinus node function or AV conduction are discovered or provoked in EP studies	1. A hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms 2. A hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms A hyperactive cardioinhibitory response to carotid sinus stimulation in the presence of vague symptoms such as dizziness, light-headedness, or both

Indication	Class I	Class II	Class III
		IIb. 1. Neurally mediated syncope with significant bradycardia reproduced by a head-up tilt with or without isoproterenol and other provocative maneuvers	3. Recurrent syncope, light-headedness, or dizziness in the absence of a hyperactive cardioinhibitory response 4. Situational vasovagal syncope in which avoidance behavior is effective

Class I: conditions for which there is evidence and/or general agreement that pacing is beneficial, useful, and effective.
Class II: conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of pacing.
Class IIa: weight of evidence/opinion is in favor of usefulness/efficacy.
Class IIb: usefulness/efficacy is less well established by evidence/opinion.
Class III: conditions for which there is evidence and/or general agreement that pacing is not useful/effective and in some cases may be harmful.
SND, sinus node dysfunction; AV, atrioventricular; LV, left ventricular; EP, electrophysiologic; HV, half-value.

ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines (writing committee to revise the ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices). *J Am Coll Cardiol*. 2008; 51:2085-2105.

3. Third-degree AV block, or **complete heart block**, may be acquired or congenital.
   a. Of patients with **congenital complete heart block**, 60% are female. Of children with congenital complete heart block, 30% to 50% of their mothers have connective tissue disease, usually systemic lupus erythematosus.
   b. Acquired AV block occurs most frequently in the seventh decade and more commonly affects males.

B. Clinical presentation

1. **Signs and symptoms**
   a. First-degree AV block is generally not a cause of symptoms.
   b. Second-degree AV block sometimes results in symptoms; however, high-grade second-degree AV block may progress to third-degree AV block, which can frequently cause symptoms.
   c. Depending on the ventricular escape rate, patients with **third-degree** AV **block** may experience **fatigue** or **syncope**.
2. **Physical findings.** The amplitude of the arterial pulse and venous waveform varies, depending on the timing of atrial filling of the ventricles.
   a. Second-degree AV block is associated with a periodic change in amplitude. In patients with **third-degree AV block**, amplitude is constantly changing, for example, periodic appearance of cannon *a* waves (large-amplitude waves in the venous pulsations seen in the neck when the atria contracts against a closed tricuspid valve).
   b. Heart sounds are similarly affected by the change in filling duration of the ventricles.
      (1) **The first heart sound** (S_1) becomes softer as the PR interval is prolonged, resulting in a soft S_1 in first-degree AV block, a progressive softening of S_1 in type I second-degree AV block, and a constantly changing S_1 in third-degree AV block.
      (2) Third-degree AV block may also result in a functional systolic ejection murmur.

C. Etiology. The causes of AV block are listed in Table 22.4; the most common cause is **idiopathic fibrosis. Acute MI** results in AV block in 14% of patients with inferior infarction and 2% of those with anterior infarction, usually within the first 24 hours.

D. Diagnostic testing

1. **First-degree AV block.** Measuring a PR interval longer than 200 milliseconds in adults and 180 milliseconds in children makes up the diagnosis. A P wave precedes each QRS, and both the P and the QRS are morphologically normal.
2. **Second-degree AV block**
   a. The diagnosis of **Mobitz type I** is made when the following criteria are met on the ECG:
      (1) Sequential and gradual prolongation of the PR interval terminated by a nonconducted P wave
      (2) Prolongation of the PR interval occurring in progressively shorter increments in "typical" Wenckebach, which results in progressive shortening of the RR intervals prior to the nonconducted atrial impulse
      (3) Duration of the pause following the nonconducted P wave is less than the sum of any two consecutively conducted beats
      (4) Decreased PR interval following the pause when compared with the prepause PR interval
      (5) "Grouped beating," a pattern of repeated groups of QRS complexes characteristic of Wenckebach block
   b. Mobitz type II second-degree AV block is less common than type I.
      (1) The PR interval is constant with a sudden nonconducted P wave (Fig. 22.2), in contrast to nonconducted premature atrial contractions that have a varying PR interval.

TABLE 22.4 Causes of Atrioventricular Block

- Drug effects
  - Digoxin
  - β-Blockers
  - Certain calcium channel blockers (nondihydropyridines)
  - Membrane-active antiarrhythmic drugs
- Ischemic heart disease
  - Acute myocardial infarction
  - Chronic coronary artery disease
- Idiopathic fibrosis of the conduction system
  - Lenegre's disease
  - Lev's disease
- Congenital heart disease
  - Congenital complete heart block
  - Ostium primum atrial septal defect
  - Transposition of the great vessels
  - Maternal systemic lupus erythematosus
- Calcific valvular disease
- Cardiomyopathy
- Infiltrative disease
  - Amyloidosis
  - Sarcoidosis
  - Hemochromatosis
- Infectious/inflammatory diseases
  - Endocarditis
  - Myocarditis (Chagas disease, Lyme disease, rheumatic fever, tuberculosis, measles, and mumps)
- Collagen vascular diseases (scleroderma, rheumatoid arthritis, Reiter's syndrome, systemic lupus erythematosus, ankylosing spondylitis, and polymyositis)
- Metabolic
  - Hyperkalemia
  - Hypermagnesemia
- Endocrine—Addison's disease
- Trauma
  - Cardiac surgery
  - Radiation
  - Catheter trauma
  - Catheter ablation
- Tumors
  - Mesothelioma
  - Hodgkin's disease
  - Malignant melanoma
  - Rhabdomyosarcoma
- Neurally mediated
  - Carotid sinus syndrome
  - Vasovagal syncope
- Neuromyopathic disorders
  - Myotonic muscular dystrophy
  - Slowly progressive X-linked muscular dystrophy

From Topol EJ, ed. *Textbook of Cardiovascular Medicine*. Philadelphia, PA: Lippincott–Raven; 1998, with permission.

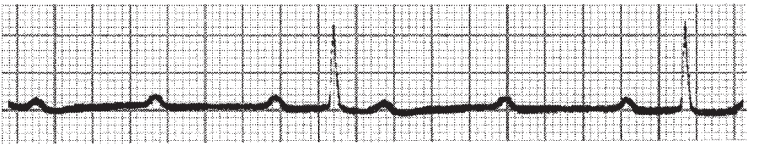

FIGURE 22.2 Mobitz type II second-degree atrioventricular block with 3:1 conduction.

(2) Each QRS complex may have multiple P waves, which are designated by the number of P waves before each conducted QRS (3:1, 4:1, etc.). The QRS complex is typically not narrow (a narrow QRS complex is suggestive of a Mobitz type I block).

3. **Third-degree AV block** (Fig. 22.3)
   a. Third-degree AV block is characterized by the identification of **complete dissociation of the atrial and ventricular electrical activities** (no temporal relationship exists between the P waves and the QRS complexes), with atrial activity more rapid than ventricular activity. Using calipers, it is possible to march out the progression of the P waves to determine the atrial rate.
   b. Third-degree AV block is only one cause of AV dissociation; **not all AV dissociation is third-degree AV block.** For example, conditions where the ventricles are depolarizing faster than the atria—such as accelerated junctional rhythm or ventricular tachycardia—also result in AV dissociation if there is a lack of retrograde conduction over the AV node.

E. **Therapy.** Patients with first-degree AV block and Mobitz type I AV block usually do not require therapy. Permanent pacing is indicated for Mobitz type II AV block and third-degree AV block. (See Table 22.3 for complete indications for pacing.)

1. Medical therapy may be used as a bridge to pacing but it has no role in long-term treatment.
   a. The principal drug used as a bridge to pacing is **atropine**,
      (1) which reduces heart block due to hypervagotonia but not due to AV nodal ischemia;
      (2) which is more useful for AV block in inferior MI than anterior MI;
      (3) which does not increase infranodal conduction (will not improve second-degree or third-degree AV block that is below the AV node);
      (4) which is ineffective in the denervated hearts of transplant patients;
      (5) which is used with caution (if at all) in Mobitz type II AV block due to a possible paradoxical decrease in heart rate (as atrial rate increases, AV conduction decreases, and a 2:1 block with an atrial rate of 80 beats/min and a ventricular rate of 40 beats/min may be converted to a 3:1 block with an atrial rate of 90 beats/min and a ventricular rate of 30 beats/min).
   b. Digoxin-specific Fab fragments may be used to treat patients with symptomatic AV blocks related to the use of digitalis. The number of vials = weight (kg) × digoxin serum concentration (ng/mL)/100.
2. **Pacing**
   a. Third-degree AV block as a complication of inferior MI is usually temporary and thus usually only requires **temporary pacing**.
   b. However, complete heart block as a result of anterior MI often requires **permanent pacing** (Table 22.3).
   c. Acquired third-degree AV block usually requires pacing, but patients with congenital third-degree AV block often have a sufficiently rapid escape rhythm to prevent symptoms and avoid permanent pacemaker implantation.

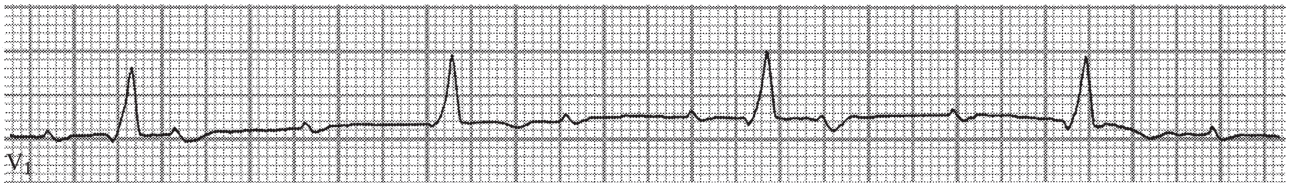

FIGURE 22.3 Third-degree atrioventricular block with sinus tachycardia and right bundle branch block.

V. JUNCTIONAL RHYTHMS. Junctional rhythms arise from the area surrounding the AV node, including the approaches to the node, the node itself, and the bundle of His. This area has an intrinsic rate of 30 to 60 beats/min and serves as an escape mechanism to prevent ventricular asystole in case of complete AV block. Junctional rhythm that is faster than the sinus rhythm is referred to as **accelerated junctional rhythm**.

A. Clinical presentation. Patients usually do not develop symptoms that are directly attributable to accelerated junctional rhythm. The **physical findings of AV dissociation may be noted** and are the same as those seen in third-degree AV block.

B. Etiology

1. Accelerated junctional rhythm is seen in approximately **10% of patients with acute MI**. More than one-half of these patients have inferior MI and about one-third have anterior infarctions.
2. Digitalis toxicity by itself does not seem to cause accelerated junctional rhythm, as evidenced in persons with normal hearts who take accidental overdoses of digoxin. **Concomitant heart disease** is required to develop accelerated junctional rhythm.
3. Other causes of accelerated junctional rhythm are valve surgery, acute rheumatic fever, direct current cardioversion, cardiac catheterization, serious infection, chronic obstructive pulmonary disease, systemic amyloidosis, and uremia with hyperkalemia.

C. ECG findings

1. **Accelerated junctional rhythm**
   a. **Unless the junctional rhythm causes retrograde activation of the atria**, the P wave is normal in morphologic characteristics. The QRS complex has a normal duration, unless there is concomitant bundle branch block. The distinguishing characteristic of accelerated junctional rhythm is the AV dissociation and changing PR interval (Fig. 22.4).
   b. **The difference between accelerated junctional rhythm and third-degree AV block is the fact that the ventricular rate is faster than the atrial rate in accelerated junctional rhythm and slower than the atrial rate in third-degree AV block**.
2. **Junctional rhythm.** In the absence of a sinus beat, the AV node can act as a backup pacemaker. The ECG findings are an absence of P waves (or retrograde P waves immediately before or after the QRS complex), a narrow QRS complex, and a rate of 30 to 60 beats/min.

D. Therapy

1. Therapy for junctional rhythm secondary to SA node failure or AV block is as previously outlined for AV conduction disturbances.
2. Patients with accelerated junctional rhythm do not usually require therapy for the arrhythmia, although management of the underlying cause is indicated.
3. Suppression of accelerated junctional rhythm may be achieved by **increasing the atrial rate with drugs** (e.g., atropine and adrenergics) or **pacing**.
4. Digoxin-induced accelerated junctional rhythm is an indication to stop digoxin but it does not usually require administration of digoxin-specific Fab fragments.

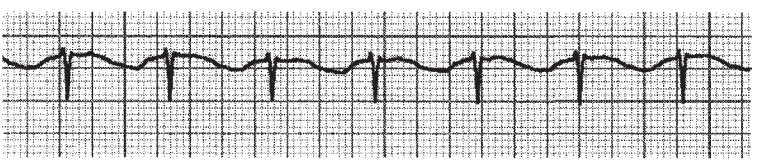

FIGURE 22.4 Accelerated junctional rhythm.

VI. INTRAVENTRICULAR CONDUCTION DISTURBANCES. Conduction disturbances due to blockage below the AV node are classified on the basis of the intraventricular conduction system. An intraventricular conduction disturbance (IVCD) does not itself cause bradyarrhythmia, but it may be associated with any of the other rhythms that cause bradycardia. When associated with an acute MI, an IVCD predicts a worse outcome.

A. Etiology

1. The causes of IVCDs are similar to those that cause AV block (Table 22.4); **idiopathic degenerative conduction disease** and **acute ischemic syndromes** are the most common causes.
2. IVCDs increase with age and affect up to 2% of individuals older than 60 years.
3. The incidence of IVCDs is increased in persons with structural heart disease, especially those with coronary artery disease.

B. ECG findings

1. The ECG findings of IVCDs are summarized in Table 22.5 and examples are presented in Figures 22.5 to 22.8. As shown, **IVCDs may be further classified by the number of fascicles they affect**.
2. **Fascicular blocks**
   a. Unifascicular blocks affect only one of the three fascicles. Examples are RBBB, left anterior fascicular block, and left posterior fascicular block (LPFB).
   b. Bifascicular block is present when conduction disturbances affect two of the fascicles, most commonly the right bundle branch and the left anterior fascicle. Approximately, 6% of these patients progress to complete heart block. RBBB with LPFB is less common, but the progression to complete heart block is more common.
   c. "Trifascicular block" is said to be present when there is a combination of bifascicular block and first-degree AV block (Fig. 22.8).

C. Therapy. Pacing is indicated in patients with bifascicular block who have intermittent symptomatic complete heart block and in patients with bifascicular or trifascicular block with asymptomatic intermittent Mobitz type II AV block (Table 22.3).

TABLE 22.5 Electrocardiographic Features for the Fascicular and Bifascicular Blocks

ECG finding	LBBB	LAFB	LPFB	RBBB	RBBB and LAFB	RBBB and LPFB
QRS axis		≥ – 45°	+90° to +120°		–60° to –120°	≥ +120°
QRS duration Leads I/aVL	≥ 120 milliseconds broad monophasic R	Normal qR	Normal rS	≥ 120 milliseconds qRS with wide terminal S	≥ 120 milliseconds qR	≥ 120 milliseconds rS
Leads II, III, and aVF		rS	qR		rS	qR
Leads V_1 and V_2	rS or QS			rsR′ or rSR′	rsR′ or rSR′	rsR′ or rSR′
Leads V_5 and V_6		S	no Q's	qRS		

ECG, electrocardiogram; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; RBBB, right bundle branch block.

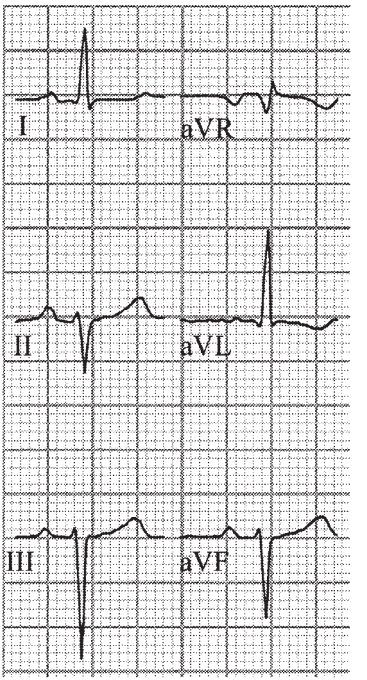

FIGURE 22.5 Left anterior hemiblock.

VII. POSTSURGICAL BRADYARRHYTHMIAS

A. Etiology. Bradyarrhythmias following cardiac surgery are common.

1. Valvular surgery and septal myectomy can cause mechanical damage to the conduction system, leading to AV blocks and IVCDs. For example, there is an approximately 7% incidence of postoperative permanent pacemaker implantation for high-grade AV block after conventional aortic valve replacement in patients with severe calcific aortic stenosis (this may be partly due to a higher prevalence of infranodal conduction system disease at baseline). Also, there is a high incidence of LBBB after septal myectomy, due to the presence of the left bundle branch in the myocardium being excised.
2. Prolonged ischemic time during cardiac transplantation can lead to sinus node damage.

B. Therapy. Because postsurgical bradyarrhythmias may be only temporary, the decision to proceed to **permanent pacing** should be made after 5 to 7 days. The same criteria listed in Table 22.3 are used to determine the need for a pacemaker. Permanent pacing is required in 2% to 3% of patients following valve surgery (when considering all types) and in upward of 10% of transplant patients.

VIII. PULSELESS ELECTRICAL ACTIVITY.

Pulseless electrical activity is defined as the absence of a pulse or blood pressure measured by usual methods, with the continued presence of electrical activity of the heart.

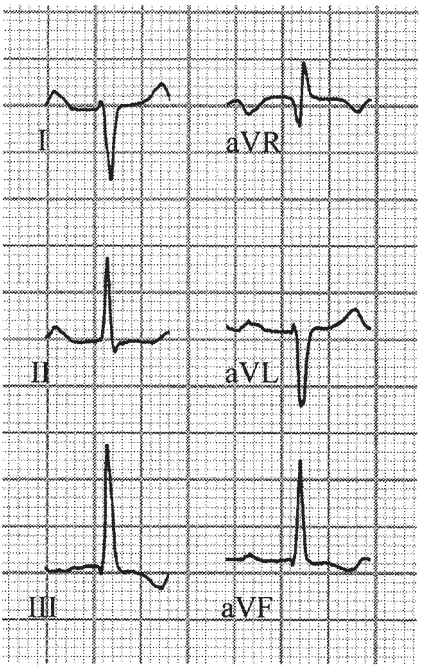

FIGURE 22.6 Left posterior hemiblock.

A. Etiology

1. Pulseless electrical activity may result from a variety of **rhythm disturbances**, such as electrical–mechanical dissociation, idioventricular rhythms, and ventricular tachycardias. When the electrical activity is organized and within the physiologic range, the term **electrical–mechanical dissociation** is used.
2. A variety of clinical situations are also associated with pulseless electrical activity, a potentially manageable condition if certain actions are undertaken rapidly (Table 22.6).

B. Therapy

1. Specific management of the underlying cause is most likely to result in a successful outcome (Table 22.6).
2. Emergency intervention should be initiated at once, including the following:
   - **(a)** Effective cardiopulmonary resuscitation (CPR) and airway management
   - **(b)** Epinephrine, 1 mg intravenous push every 3 to 5 minutes
   - **(c)** A one-time intravenous push of 40 IU of vasopressin may be considered as an alternative to epinephrine during the first or second round of advanced cardiac life support
   - **(d)** Atropine is no longer recommended for routine administration during advanced cardiac life support for pulseless electrical activity, as per 2010 ACC/AHA guidelines.
   - **(e)** Discovery and correction of the underlying reason for the pulseless electrical activity (see Table 22.6) remains the paramount concern along with performing

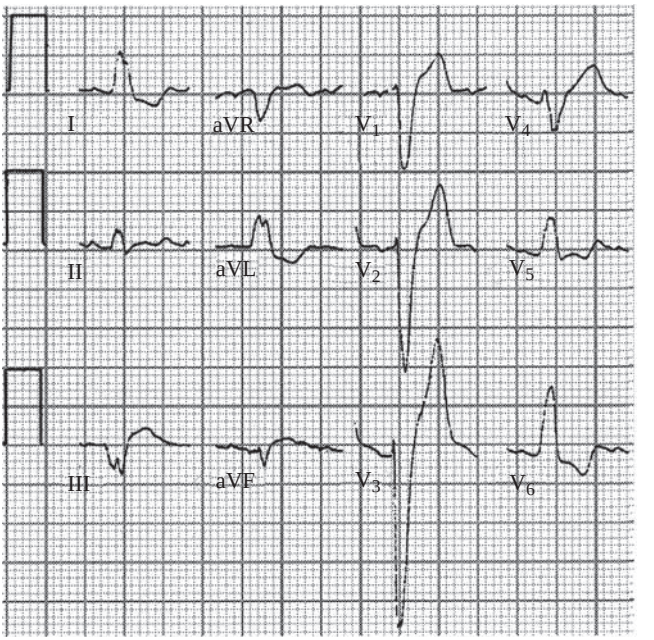

FIGURE 22.7 Left bundle branch block.

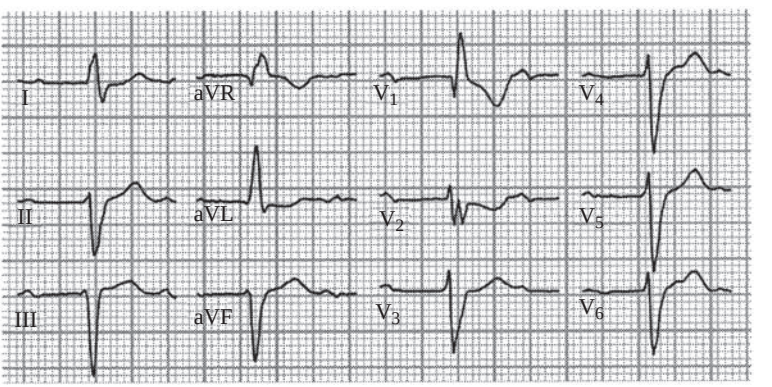

FIGURE 22.8 First-degree atrioventricular block with right bundle branch block and left anterior hemiblock.

effective CPR. The "H's and T's" of hypoxia, hypovolemia, hypothermia, hyperkalemia, acidosis ("hyper-H+"), tension pneumothorax, thrombosis (coronary or pulmonary), tamponade, and toxins must be considered and addressed as soon as possible.

TABLE 22.6 Conditions That Cause Pulseless Electrical Activity

Condition	Clues	Management
Hypovolemia	History and flat neck veins	Volume infusion
Hypoxia	Cyanosis, blood gases, and airway problems	Ventilation
Cardiac tamponade	History (trauma, renal failure, and malignancy), no pulse with CPR, vein distention; impending tamponade—tachycardia, hypotension, and low pulse pressure	Pericardiocentesis
Tension pneumothorax	History (asthma, ventilator, chronic obstructive pulmonary disease, and trauma), no pulse with CPR, neck vein distention, and tracheal deviation	Needle decompression
Hypothermia	History of exposure to cold, central body temperature, and ECG	Gradual warming
Massive pulmonary embolism	History and no pulse felt with CPR	Pulmonary arteriogram, surgical embolectomy, and thrombolytics
Drug overdose (tricyclics, digoxin, β-blockers, and calcium channel blockers)	Bradycardia, history of ingestion, empty bottles at the scene, pupils, and neurologic examination	Drug screens, intubation, lavage, activated charcoal, and lactulose per local protocols
Hyperkalemia	History of renal failure, diabetes, recent dialysis, medications, and ECG	Calcium chloride (immediate); then combination of insulin, glucose, and sodium bicarbonate; then sodium polystyrene sulfonate/sorbitol; and dialysis (long term)
Preexisting acidosis	Renal failure	Sodium bicarbonate and hyperventilation
Acute massive MI	History, ECG and enzymes	Treatment for cardiogenic shock

CPR, cardiopulmonary resuscitation; ECG, electrocardiogram; MI, myocardial infarction.

IX. ASYSTOLE

A. Clinical presentation. Asystole is defined as the absence of myocardial electrical activity. *It should be confirmed by switching between several leads or changing the position of the defibrillation paddles.*

1. Most patients with asystole present in a code situation. Persons outside of the hospital who are found to have asystole by the initial responding team usually have it as a result of **profound myocardial ischemia**. The possibility of a successful outcome in this situation is extremely small.

2. Hospital inpatients monitored by telemetry, on the other hand, may have a favorable outcome.

B. Etiology. Asystole may be due to profound parasympathetic suppression of both atrial and ventricular activities, stunning of the myocardium due to electrical defibrillation, complete heart block, or prolonged myocardial ischemia. Also, many of the causes of pulseless electrical activity may also lead to asystole, and the same search for obvious and immediately reversible causes is warranted (Table 22.6).

C. Therapy. Management consists of effective **CPR, airway protection**, and **a similar management algorithm to** pulseless electrical activity.

1. Routine shocking is strongly discouraged. Electrical shocks have not been demonstrated to have any benefit in the management of asystole and may in fact produce a stunned myocardium, leading to a delay in the return of a rhythm.
2. Pacing for asystole is controversial. If pacing is to have any effect, it must be initiated early. Patients with asystole due to myocardial ischemia are unlikely to respond to pacing, but those with asystole due to other causes might respond.
3. As with the 2010 revised guidelines for management of pulseless electrical activity, atropine is no longer recommended for routine use in the resuscitation of the asystolic patient.

X. CAROTID SINUS HYPERSENSITIVITY. Carotid sinus hypersensitivity, defined as a sinus pause of 3 seconds or more and/or a drop in blood pressure of 50 mm Hg or more with carotid sinus massage, is common, affecting up to one-third of older men with coronary artery disease. Carotid sinus hypersensitivity may be purely cardioinhibitory, purely vasodepressive, or a combination of both. **Carotid sinus syndrome** is present when carotid sinus hypersensitivity is accompanied by syncope or near syncope.

A. Etiology and pathophysiology

1. The **cause of carotid sinus hypersensitivity and carotid sinus syndrome is unknown**. It is more common in older individuals, particularly those with atherosclerotic disease. Carotid sinus syndrome may be precipitated by the patient stretching his or her neck (such as with shaving or turning the head) or wearing a tight collar, but often a precipitating event cannot be found.
2. Sites of potential lesions causing carotid sinus hypersensitivity are the sternocleidomastoid muscle, the central nervous system, and the feedback loops between the cardiovascular and the central nervous systems.
3. It has been demonstrated that the **carotid sinus function is intact** and the sinus is not hypersensitive in the true sense. Some investigators have suggested that carotid sinus syndrome be renamed carotid sinus irritability to better reflect its pathophysiology.

B. Diagnostic testing. A patient with suspected carotid sinus hypersensitivity/carotid sinus syndrome should be tested lying down with ECG and blood pressure monitoring.

1. Carotid sinus massage is performed by placing firm manual pressure over the carotid sinus located at the bifurcation of the carotid artery for not more than 5 seconds. Only one sinus at a time is compressed, and the temporal artery should be lightly palpated to ensure that complete occlusion of the artery does not occur.
2. Potential risks of carotid sinus massage are transient ischemic attack and stroke. This test should not be performed if a carotid bruit is present. Tilting the patient to an upright position will increase the diagnostic yield of the test but it may also result in false-positive outcomes.

C. Therapy

1. Carotid sinus hypersensitivity by itself generally does not require treatment. However, therapy is warranted if carotid sinus hypersensitivity is demonstrated to be the cause of syncope or near syncope.

2. For purely cardioinhibitory or the mixed type of carotid sinus syndrome, the therapy of choice is pacing (Table 22.3).
3. Management of vasodepressive carotid sinus syndrome is more difficult, and pacing is generally ineffective.

ACKNOWLEDGMENTS: *The author thanks Drs. Christopher Cole, Gregory Bashian, and Oussama Wazni for their significant contributions to earlier editions of this chapter.*

CHAPTER 23

Edmond M. Cronin

Sudden Cardiac Death

I. DEFINITION AND EPIDEMIOLOGY. Sudden cardiac death (SCD) is defined as death following cardiac arrest in a patient with or without known preexisting heart disease in whom the mode and time of death are unexpected (1). The generally accepted timeframe between the onset of symptoms and loss of consciousness is 1 hour, although some patients who receive medical interventions may live for much longer after the initiating event before expiring. If the patient survives the event, due to defibrillation or spontaneous recovery, it is labeled sudden cardiac arrest (SCA). The incidence of SCD in the United States is estimated at 460,000 cases per annum, accounting for 10% to 15% of all deaths from natural causes and about 50% of all cardiac deaths. SCD exhibits a bimodal age distribution with peaks between birth and 6 months of age and then rises steadily from age 30. A male preponderance is observed in all age groups, narrowing after age 65, and is attributable to an increased incidence of coronary artery disease (CAD). While the absolute risk of SCD is greater among high-risk populations, most SCDs occur in patients who have not been identified as being at risk, being the first presentation of cardiovascular disease in approximately 25% of patients.

It is likely that ventricular fibrillation (VF) or ventricular tachycardia (VT) is the initiating rhythm in most cases of SCA. As the time from onset and rhythm identification increases, the proportion of VF decreases. This suggests that asystole and pulseless electrical activity (PEA) are frequently the result of prolonged VF and resultant ischemia and hypoxia. However, a significant proportion of SCA is due to bradyarrhythmias and pump failure. The proportion of these deaths is slightly higher in patients with advanced heart failure, although tachyarrhythmias still predominate.

II. CAUSES OF SCD

A. Coronary artery disease accounts for 80% or more of episodes of SCD in Western societies, and SCD is the first presentation of CAD in 20% to 25% of patients. However, the extent to which acute ischemia plays a role in initiating a trigger for SCD is unclear. Autopsy data have demonstrated a recent occlusive thrombus in only about 15% to 20% of patients, while evidence of a remote infarct is identified in 40% to 70% of cases. The majority (80%) of SCD episodes in patients with CAD are considered to be primary (i.e., no precipitating factor can be identified), whereas secondary causes like myocardial ischemia/infarction, drug toxicity or proarrhythmia, decompensated heart failure, or electrolyte imbalance can be identified in the minority. Patients with reduced left ventricular ejection fraction (LVEF) and frequent premature ventricular contractions (PVCs) are identified as a particularly high-risk subgroup. A study of patients implanted with a loop recorder with recent myocardial infarction (MI) and ejection fraction (EF) ≤ 40% found that the terminal rhythm was VF in 86% of sudden deaths, and 50% of all deaths, with bradyarrhythmias in the remaining 50%.

B. Cardiomyopathies

1. **Dilated cardiomyopathy (DCM).** Patients with DCM represent the second largest group of patients who experience SCD, accounting for approximately 10% of cases. The annual mortality from DCM is 11% to 15%, with SCD accounting for about 30% of all deaths in this population. The presence of reduced LVEF and syncope are markers of a high risk of SCD in these patients. There is also a higher incidence of sudden deaths related to bradyarrhythmias and PEA in patients with advanced disease.
2. **Hypertrophic cardiomyopathy (HCM).** The incidence of SCD in patients with *HCM* is 2% to 4% per year in adults and 4% to 6% per year in children and adolescents. Risk factors that identify a high-risk population in patients with HCM include prior SCA, family history of SCD, sustained or nonsustained VT (NSVT), syncope, a drop in blood pressure with exercise, and septal hypertrophy ≥ 30 mm. Myocardial scar, detected by late gadolinium enhancement on magnetic resonance imaging (MRI), is also emerging as a predictor of risk. SCD usually results from ventricular arrhythmias, but occasionally it may be precipitated by atrial fibrillation, bradyarrhythmias, or myocardial ischemia.
3. **Arrhythmogenic right ventricular dysplasia (ARVD).** *ARVD* is a rare genetic disorder characterized by heart failure, ventricular arrhythmias, and SCD. Mutations involving the desmosome are manifested by fibrofatty infiltration of the right ventricle. The incidence of SCD is approximately 2% per year and is mainly due to ventricular tachyarrhythmia. Patients are identifiable by right bundle branch block (RBBB), T-wave inversion in V_1 through V_3 and epsilon waves on the electrocardiogram (ECG), regional right ventricular akinesia, dyskinesia, or aneurysm on echo or MRI, and findings on endomyocardial biopsy.

C. The channelopathies

1. **The congenital long QT syndrome (LQTS).** *LQTS* is a familial disease with a prevalence of about 1:2,000, characterized by an abnormally long QT interval, leading to the development of early afterdepolarizations and torsades de pointes.

The two variants of the syndrome include the more common autosomal dominant form (Romano-Ward syndrome) and the less common recessive form (Jervell and Lange-Nielsen syndrome), which is associated with congenital deafness. To date, mutations at 12 different LQTS susceptibility genes have been identified. The most common, accounting for over 50% of cases, is a mutation in *KCNQ1*, which encodes the α-subunit of the potassium channel conducting the slow delayed rectifier current (I_{Ks}). This mutation produces LQT1, which is characterized clinically by broad-based T waves and exercise-induced arrhythmic events (especially swimming). LQT2 (35% to 40% of cases) is caused by mutations in the *KCNH2* gene encoding the HERG protein (I_{Kr} current) and presents with low-amplitude, notched T waves and auditory arrhythmogenic triggers. LQT3 is caused by a gain-of-function mutation in the sodium channel gene *SCN5A* and manifests a long, isoelectric ST segment and SCD events during sleep.

The mortality rate for LQTS is estimated to be about 1% per year. High-risk patients include those with a corrected QT interval > 500 milliseconds, a history of syncope or SCA, male sex in children and female sex in adults (especially after menopause), and the LQT2 or LQT3 genotype. It has been postulated that 11% to 13% of sudden infant death syndrome cases could be caused by LQTS. All patients are treated with β-blocker therapy; however, genotype-specific and individualized therapies are evolving. Symptomatic patients who are either refractory to or intolerant of medical therapy, or who have other high-risk markers for SCD, should be considered for implantable cardioverter–defibrillator (ICD) implantation and left cardiac sympathetic denervation. It seems increasingly likely that many patients who suffer cardiac events due to drug-induced or other acquired QT prolongation have a *forme fruste* of LQTS.

The very rare *short QT syndrome* is caused by mutations in genes encoding the potassium channel, resulting in shortening of the action potential duration and vulnerability to VF.

2. **Brugada syndrome.** The *Brugada syndrome* is an autosomal dominant arrhythmogenic disorder caused by mutations in the *SCN5A* gene encoding the cardiac sodium channel, which predisposes patients to develop polymorphic VT or VF. The arrhythmias commonly occur at rest or during sleep, and the risk of SCA is up to 30% at 3 years in untreated symptomatic patients. Incomplete RBBB with coved ST elevation in the right precordial leads is diagnostic and, although often transient, may be elicited by a drug challenge. Atrial fibrillation and conduction abnormalities are frequently associated. Symptomatic patients (syncope or SCA) should undergo ICD implantation; risk stratification for asymptomatic patients is controversial.
3. **Catecholaminergic polymorphic ventricular tachycardia (CPVT)** is due to mutations in the ryanodine receptor and calsequestrin and results in a malignant phenotype of bidirectional VT during emotional or physical stress. Treatment is with β-blockers and ICD, and recent evidence suggests an emerging role for flecainide.

D. Others. The risk of SCD is also higher in patients with *Wolff-Parkinson-White (WPW) syndrome*, especially if they have rapidly conducting accessory pathways, when atrial fibrillation can be associated with very rapid ventricular rates and degeneration to VF. An RR interval ≤ 220 milliseconds during spontaneous AF indicates a higher risk. The incidence of SCD is 0.05% to 0.1% per year and is higher in males in their second and third decades, but the phenomenon is easily identifiable and manageable. When no cause of SCA can be found, the label *idiopathic VF* is applied. In some cases, VF is triggered by a PVC which is amenable to catheter ablation. Recent evidence suggests that *early repolarization* on ECG denotes a higher risk of SCD in the presence of proarrhythmic triggers, and the clinical implications of this are still being clarified. Some of the other cardiac and noncardiac causes of SCD are presented in Table 23.1.

TABLE 23.1 Some Other Conditions with an Increased Risk of Sudden Cardiac Death

Cardiac	Noncardiac
Cardiac vascular	Neurologic
Coronary artery anomalies	Epilepsy
Coronary artery embolism	Hereditary muscular dystrophies
Coronary arteritis (polyarteritis nodosa and Kawasaki syndrome)	Friedreich's ataxia
Coronary artery dissection	Central nervous system injury
Coronary spasm	Respiratory
Myocardial bridging	Asthma
Valvular and great vessels	Obstructive sleep apnea
Severe aortic stenosis	Massive pulmonary embolism
Severe mitral regurgitation	Pulmonary hypertension
Prosthetic valvular obstruction or dehiscence	Endocrine and metabolic
Ruptured sinus of Valsalva aneurysm	Diabetes mellitus
Aortic dissection	Acromegaly
Electrophysiologic	Electrolyte disturbances
Progressive cardiac conduction disease (Lev-Lenegre disease)	Acid–base disturbances
Myocardial	Renal
Left ventricular hypertrophy	Chronic kidney disease
Infiltrative disease (sarcoid and amyloid)	Hemodialysis
Apical ballooning syndrome	Psychiatric/psychological
Myocarditis	Depression
Congenital	Anxiety
Eisenmenger physiology	Anorexia nervosa
Late after surgical repair, especially of tetralogy of Fallot	Intense emotion
Trauma	Situational
Cardiac tamponade	Intense exercise and athletes
Commotio cordis	Drugs
	Antiarrhythmic drugs
	Typical and atypical antipsychotics
	Other QT-prolonging drugs
	Drug–drug interactions
	Cigarette smoking
	Cocaine

III. DIAGNOSTIC AND PROGNOSTIC TESTING. Survivors of SCA should have a detailed cardiovascular evaluation. Reversible precipitating factors must be identified and corrected. Underlying diseases must be identified and managed, and the risk of recurrent SCD must be determined. Diagnostic and prognostic testing appropriate for the survivor of SCA includes the following:

A. ECG for the evidence of MI or ischemia, intraventricular conduction delay, accessory pathway (WPW syndrome), prolonged QT interval, epsilon waves, Brugada pattern, and left ventricular hypertrophy.

B. Laboratory data to rule out reversible causes, such as cardiac biomarkers (creatine kinase–myocardial band, troponin T, and troponin I), abnormal electrolytes, antiarrhythmic drug levels for toxicity, and urine screening for illicit drugs such as cocaine.

C. ECG monitoring to assess frequency, duration, and symptomatology of arrhythmias.

D. **Twenty-four-hour ambulatory electrocardiography** during normal activities can be useful in predicting the risk of recurrent SCA.

E. **Echocardiography** for the assessment of left ventricular function, valvular disease, cardiomyopathy, and hypertrophy. Nuclear or angiographic determinations of left ventricular function may be used but do not provide as much information as echocardiography. The LVEF continues to be the most potent predictor of SCD, behaving as a continuous variable with markedly increased risk < 40%. However, nonsudden death also increases with declining EF, meaning that the likely mode of death cannot be predicted. LVEF is also limited by poor sensitivity—from 22% to 59% in studies in the last decade.

F. **Coronary angiography** for the assessment of CAD or coronary anomalies.

G. **Exercise or pharmacologic stress testing** with radionuclide imaging or echocardiography if CAD is present and myocardial ischemia and/or viability is in question.

H. **Electrophysiologic (EP) testing** has a limited role in assessing the survivor of SCA. Given its low sensitivity, a negative test does not exclude recurrent SCA, and almost all patients who survive SCA are in any case candidates for an ICD. Although EP testing can be performed to guide programming of the ICD, this is rarely done in practice. Voltage mapping has been used to corroborate a diagnosis of ARVD, and mapping and ablation are essential in the management of patients with WPW and selected patients with cardiomyopathy and VT. Emerging applications of ablation in ARVD and Brugada syndrome deserve further study.

I. **Cardiac MRI.** Particularly for the patient with normal left ventricular function, cardiac MRI may be useful to evaluate for arrhythmogenic right ventricular cardiomyopathy and to investigate left ventricular hypertrophy.

J. Drug challenge with flecainide, procainamide, or ajmaline to provoke the Brugada pattern should be considered in all SCA survivors where the above tests do not reveal a cause. Epinephrine infusion or exercise testing has been used to diagnose LQT1 and CPVT.

K. Genetic testing for the channelopathies, HCM, and ARVD is becoming increasingly comprehensive; however, many as yet unidentified mutations are postulated to exist. At present, only 21% of patients with Brugada syndrome and 52% with ARVD have an identifiable causative mutation. Testing in cases where a clear phenotype has not been established, or is not suggestive of a genetic disorder, is discouraged, as many variants are of uncertain significance. A positive genetic test is useful and facilitates family screening, but a negative test is not.

IV. THERAPY

A. Acute therapy for SCA

1. **Cardiopulmonary resuscitation (CPR).** Early response is crucial. The two most critical components of out-of-hospital cardiac resuscitation are the availability of a rapid response system and citizen bystander CPR. Survivors of SCA are more likely to be discharged from the hospital if the arrest is witnessed and they receive early CPR from bystanders. There is an increasing drive to train police personnel, students, and the general public in resuscitation techniques, focusing on high-quality, uninterrupted chest compressions.
2. **Automated external defibrillator (AED) and public access defibrillation.** An AED is designed to be used by emergency personnel and lay rescuers with minimal or no training, particularly for victims of out-of-hospital SCA. The device monitors the patient's ECG via self-adhesive defibrillation electrode pads applied to the chest wall and is programmed with a VF detection algorithm. When the device detects VF, an alarm is emitted, followed by delivery of a defibrillation shock or an indicator for the rescuer to press a button to deliver the shock. Availability of these devices results in more rapid delivery of defibrillation and improved survival to hospital discharge in several large trials. Provision of AEDs for public access defibrillation in airports, sporting facilities, and shopping

malls has the potential to have a significant impact on survival of out-of-hospital SCA. Home AEDs have not been shown to increase survival.

3. **Advanced cardiac life support (ACLS).** Unlike AEDs, incorporation of ACLS techniques into prehospital care has not been shown to improve survival in out-of-hospital SCA. Continuous refinements in ACLS algorithms continue to be made, including an emphasis on high-quality CPR with minimal interruption.
4. **Post–cardiac arrest hospital care.** Initial management is focused on establishing and maintaining hemodynamic stability and supportive care. Amiodarone or lidocaine (especially if ischemia is suspected as the trigger) is often used to prevent further ventricular tachyarrhythmias. Therapeutic hypothermia for patients who remain unconscious after resuscitation confers a modest improvement in neurologic outcome. Immediate coronary angiography, with revascularization if indicated, may improve survival in patients in whom an ischemic etiology is suspected. Further diagnostic testing is described above.

B. Primary prevention of SCD

1. **Identifying individuals at risk for SCD.** No single factor has been identified that accurately predicts the occurrence of SCD, although combinations of factors have been more useful. In general, the specificity and positive predictive value of these tests are poor, whereas the negative predictive value is much better (particularly for combinations of tests). Overall, the most potent predictor of survival continues to be LVEF, but other factors may aid prognostication and guide subsequent therapy. Other tools for predicting the risk of SCD, such as EP testing, ambulatory electrocardiography, signal-averaged electrocardiography (SAECG), baroreflex sensitivity, heart rate variability (HRV), and T-wave alternans, have been used to identify high-risk groups, but none have been shown to be of convincing value. Although a combination of different tests can improve sensitivity and specificity, the positive predictive value remains modest.
2. **Pharmacologic agents and surgical/percutaneous revascularization.** Because the majority of episodes of SCD occur in patients with CAD, agents that reduce myocardial ischemia (β-blockers), prevent or limit the extent of MI, and alter ventricular remodeling after MI (ACE inhibitors and aldosterone antagonists) have all been shown to reduce the incidence of SCD. Although there is no direct evidence of a role for antiplatelets or statins in reducing SCD, such an effect is likely, given the reduction in mortality in several broad populations. Early studies of surgical myocardial revascularization showed a reduction in SCD for patients with triple-vessel CAD and left ventricular dysfunction compared with those patients treated medically. Fibrinolysis and percutaneous coronary intervention also reduce SCD in patients with MI. Catheter ablation of VT has a role in select patient populations, particularly in patients with incessant arrhythmias, despite antiarrhythmic drug and/or implantable device therapy.

   More than 40 years ago, complex ventricular ectopy in survivors of MI was recognized as a risk factor for SCD. Suppression of ventricular ectopy with antiarrhythmic drugs in such patients was, therefore, thought to be beneficial. However, the Cardiac Arrhythmia Suppression Trial (CAST) demonstrated that the proarrhythmic effects of class Ic antiarrhythmic drugs are greater than the benefit achieved through ectopy suppression in the post-MI population, resulting in a 2.6-fold increased mortality. Excess mortality was also demonstrated in survivors of MI with poor left ventricular function taking the class II/III agent sotalol in the Survival With Oral *d*-Sotalol (SWORD) study and with mexiletine.

   To date, of all the antiarrhythmic drugs only amiodarone has been shown to reduce SCD in some populations. Initial small trials of amiodarone therapy for survivors of MI, and meta-analyses of these trials, suggested reduced SCD mortality and the larger but unblinded Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA) study appeared to corroborate

this finding. However, several prospective, placebo-controlled trials did not. The Survival Trial of Amiodarone in Patients with Congestive Heart Failure (CHF-STAT) failed to demonstrate a significant reduction in either SCD or all-cause mortality in a largely male population with heart failure, EF ≤ 40%, and frequent PVCs. Although the European Myocardial Infarct Amiodarone Trial (EMIAT) demonstrated a 35% reduction in arrhythmic deaths in a population with recent MI, there was no difference in all-cause mortality. The Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) similarly reported a reduction in resuscitated VF or arrhythmic death in survivors of MI with frequent ventricular ectopy, but no difference in all-cause mortality. Lastly, there was no difference in the primary end point of all-cause mortality between amiodarone and placebo in the medical treatment arm of the large Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). The newer benzofuran derivative, dronedarone, also reduced SCD in the pivotal ATHENA trial of patients with atrial fibrillation and additional risk factors, but increased all-cause mortality in patients with severe heart failure in the Antiarrhythmic Trial with Dronedarone in Moderate to Severe CHF Evaluating Morbidity Decrease (ANDROMEDA). Mexiletine showed a trend toward increased mortality, and dofetilide and azimilide had no effect on all-cause mortality or SCD in patients with recent MI in large controlled studies.

In summary, amiodarone reduces SCD but not all-cause mortality in patients with heart failure or recent MI, and several other antiarrhythmics, including class Ic agents, mexiletine, dronedarone, and sotalol, may increase mortality in this population.

3. **Implantable devices.** In light of the inefficacy and even hazards of antiarrhythmic drugs for the prevention of SCD, attention has shifted to the ICD. Since its introduction by Mirowski in 1980, technical refinements have paralleled a series of clinical trials which extended indications to primary prevention in select populations. The Multicenter Automatic Defibrillator Implantation Trial (MADIT) demonstrated a 54% relative risk reduction in all-cause death versus usual care in 196 patients with prior MI, New York Heart Association (NYHA) class I–III heart failure, EF ≤ 35%, NSVT, and inducible, nonsuppressible, ventricular arrhythmia during EP study (EPS). The Multicenter Unsustained Tachycardia Trial (MUSTT) randomized patients with coronary artery disease, EF ≤ 40%, NSVT, and inducible VT/VF to receive EP-guided antiarrhythmic drug therapy, with or without an ICD, or no therapy. The 27% reduction in arrhythmic death or cardiac arrest in the EP-guided drug therapy arm was entirely driven by a 76% reduction in patients with ICDs, with no difference between drug therapy and no therapy. Given the modest predictive value of EPS, MADIT II dispensed with inducible VT as an inclusion criterion and enrolled patients with prior MI on the basis of an EF ≤ 30%. This randomized comparison of ICD with usual care demonstrated a 31% relative risk reduction in all-cause mortality over an average follow-up of 20 months. MADIT, MUSTT, and MADIT II all enrolled patients with prior MI. While the underpowered Amiodarone Versus Implantable Cardioverter-Defibrillator (AMIOVIRT) and Cardiomyopathy Trial (CAT) failed to show a benefit of ICDs over medical therapy in patients with nonischemic cardiomyopathy (NICM), the results of the Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial extended primary prevention ICD therapy to these patients. In patients with NICM, heart failure, EF ≤ 35%, and NSVT or frequent PVCs, a nonsignificant reduction in all-cause mortality was observed, with a significant reduction in SCD. The larger SCD-HeFT randomized 2,521 patients with ischemic cardiomyopathy (52%) or NICM (48%), EF ≤ 35%, and NYHA functional class II or III heart failure to receive conventional therapy plus placebo,

amiodarone, or a single lead ICD. ICD therapy reduced all-cause mortality by 23% compared with placebo, whereas amiodarone was not associated with any benefit. These trials, and SCD-HeFT in particular, ushered in the current era of primary prevention ICDs for patients risk-stratified largely on the basis of EF.

The limitations of ICDs have also been defined by clinical trials. The Coronary Artery Bypass Graft (CABG) Patch Trial demonstrated that primary prevention ICD implantation at the time of CABG in patients with preoperative left ventricular dysfunction (EF ≤ 35%) and an abnormal SAECG did not improve the overall survival, despite reducing arrhythmic deaths. The lower event rates in the CABG Patch Trial were consistent with earlier evidence that CABG reduces the risk of SCD in this population, negating the protective effect of the ICD.

MADIT, MUSTT, and MADIT II studied patients with remote (> 3 weeks) ischemic events. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) assessed whether the benefits of ICD therapy would also be seen early after MI. The trial enrolled patients 6 to 40 days post-MI with EF < 35% and impaired HRV or elevated average 24-hour heart rate and randomized them to receive an ICD or no ICD. Although ICD therapy reduced arrhythmic death, this was offset by an increase in nonarrhythmic death in the ICD group, so there was no difference in all-cause mortality over 30 months of follow-up. These results were confirmed by the larger Immediate Risk Stratification Improves Survival (IRIS) trial, which enrolled a similar population. Taken together, IRIS and DINAMIT suggest that while ICDs prevent SCD in high-risk patients early post-MI, this merely changes the mode of death to nonsudden death, without affecting the overall survival. This is supported by a secondary analysis of DINAMIT, which showed that the risk of nonsudden death in the ICD group was 4.8-fold higher in those who had received an appropriate shock. The above findings have been incorporated into the Centers for Medicare and Medicaid Services (CMS) coverage determination for ICDs, which excludes patients with MI within 40 days and surgical or percutaneous revascularization within 3 months of ICD implantation. A wearable defibrillator is available for temporary use, while diagnostic testing is ongoing, or during periods of transient elevated risk.

4. **Cardiac resynchronization therapy (CRT).** Approximately 30% of patients with advanced heart failure (EF ≤ 35%) have an associated ventricular conduction delay resulting in a QRS duration ≥ 120 milliseconds and are candidates for CRT. Biventricular pacing has been shown to improve survival, quality of life, exercise capacity, and EF in patients with advanced CHF. Extended follow-up data from the Cardiac Resynchronization in Heart Failure (CARE-HF) trial also reported a significant 46% reduction in SCD in patients with CRT without a defibrillator when compared with no CRT. However, a significant number of SCDs occurred in the CRT group, some of which might conceivably have been prevented by a defibrillator. The only large randomized trial comparing CRT with a defibrillator (CRT-D), CRT without (CRT-P), and no device was the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) trial. While not powered to detect a difference between CRT-D and CRT-P, a nonsignificant 50% decrease in SCD was seen with CRT-D in patients with NYHA class III or IV CHF, EF ≤ 35%, and a QRS duration ≥ 120 milliseconds. These data suggest that CRT-D should be considered for most patients eligible for biventricular pacing.

C. Secondary prevention

1. **Pharmacologic agents.** As with primary prevention of SCD, the disappointing efficacy and safety of class I antiarrhythmic drugs shifted attention to other antiarrhythmic drugs for the secondary prevention of SCD. In the Cardiac Arrest in Seattle Conventional Versus Amiodarone Drug Evaluation (CASCADE) study,

amiodarone reduced cardiac death, arrest, and ICD shocks compared with conventional class I antiarrhythmic drugs in a secondary prevention population. In addition, the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) trial demonstrated that the class II/III antiarrhythmic drug sotalol was superior to six class I agents guided by EP testing or Holter monitoring in preventing all-cause, cardiac, and arrhythmic mortality in patients with a history of VT/VF, SCA, or syncope. However, emergence of the ICD led to randomized trials comparing the efficacy of best medical therapy and ICDs for the secondary prevention of SCD.

2. **Implantable devices.** The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial studied the efficacy of ICD therapy versus the antiarrhythmic drugs amiodarone or sotalol for the secondary prevention of SCD in patients with resuscitated VF or sustained VT plus either syncope or EF ≤ 40% and hemodynamic compromise during VT. Inducible arrhythmias were not required for inclusion, and only sotalol therapy was guided by EP testing (only 2.6% of patients randomized to antiarrhythmic drug therapy were discharged on sotalol). ICDs reduced all-cause mortality by 31% at 3 years of follow-up.

   Two other large trials of ICDs for secondary prevention of SCD that ran concurrently with AVID reported similar results. The Cardiac Arrest Study Hamburg (CASH) found that ICDs conferred a nonsignificant 23% reduction in all-cause mortality when compared with amiodarone or metoprolol in patients with resuscitated cardiac arrest due to documented VT/VF. The propafenone arm of the study was terminated early after an interim analysis showed excess mortality compared with the ICD group. The Canadian Implantable Defibrillator Study (CIDS) enrolled a similar population as the AVID trial randomizing patients with resuscitated VF, sustained VT with syncope or hemodynamic compromise and EF ≤ 35%, or unmonitored syncope with subsequent spontaneous or induced VT to ICD or amiodarone therapy. Over a mean follow-up period of 3 years, a nonsignificant 19.7% relative risk reduction in all-cause mortality was observed, as well as a nonsignificant 32.8% reduction in SCD. Each of the above studies excluded patients with a transient or reversible cause of ventricular arrhythmias, such as MI within 72 hours, or electrolyte imbalances. A meta-analysis of these three trials confirmed a significant 28% reduction in the relative risk of death with the ICD, which was due largely to a 50% reduction in SCD.

   Of considerable interest is evidence that patients screened for the AVID trial but thought to have a transient or reversible cause of SCA, and who were not entered in the trial but followed in a registry, had poor long-term survival similar to those patients who were also ineligible for the trial but known to be at high risk for SCD. These data emphasize the need for meticulous evaluation of every SCA survivor and careful consideration of whether SCA was due to a cause that was not only transient and reversible but also preventable in the future.

D. Summary: antiarrhythmic drugs versus ICDs. Current guidelines for ICD therapy are summarized in Table 23.2. From the available data, there is good evidence that many antiarrhythmic drugs are not efficacious and may be harmful in the primary prevention of SCD, and antiarrhythmic drugs (apart from β-blockers) are not indicated for this purpose. ICD therapy has been proven to be highly effective in the termination of malignant ventricular arrhythmias and is more effective than antiarrhythmic medications for the prevention of SCD in patients with ischemic or nonischemic heart failure and an EF ≤ 35%. Patients with prolonged QRS duration, especially with LBBB, should also be considered for CRT. The most powerful predictor of SCD risk in this population remains LVEF, and other methods such as EP testing and SAECG may give additional information but are neither sensitive nor specific enough to select patients for ICD therapy. Specific antiarrhythmics may have niche uses in high-risk patients with genetic diseases predisposing

TABLE 23.2 Indications for Implantable Cardioverter–Defibrillator Therapy

Class I

1. Survivors of cardiac arrest due to VF or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes
2. Structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable
3. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced during electrophysiologic study
4. LVEF ≤ 35% due to prior MI, at least 40 d post-MI, and NYHA class II or III
5. Nonischemic DCM, LVEF ≤ 35%, and NYHA class II or III
6. LV dysfunction due to prior MI, at least 40 d post-MI, LVEF ≤ 30%, and NYHA class I
7. Nonsustained VT due to prior MI, LVEF ≤ 40%, and inducible VF or sustained VT during electrophysiologic study
8. Symptomatic sustained VT in association with congenital heart disease after hemodynamic and electrophysiologic evaluation

Class IIa

1. Unexplained syncope, significant LV dysfunction, and nonischemic DCM
2. Sustained VT and normal or near-normal ventricular function
3. Hypertrophic cardiomyopathy with one or more major risk factors for SCD
4. ARVD/C with one or more risk factors for SCD
5. Long QT syndrome with syncope and/or VT while receiving β-blockers
6. Nonhospitalized patients awaiting heart transplantation
7. Brugada syndrome with syncope
8. Brugada syndrome with documented VT that has not resulted in cardiac arrest
9. Catecholaminergic polymorphic VT with syncope and/or documented sustained VT while receiving β-blockers
10. Cardiac sarcoidosis, giant cell myocarditis, or Chagas disease
11. Congenital heart disease with recurrent syncope of undetermined origin in the presence of either ventricular dysfunction or inducible ventricular arrhythmias during electrophysiologic study

Class IIb

1. Nonischemic heart disease, LVEF ≤ 35%, and NYHA class I
2. Long QT syndrome with risk factors for SCD
3. Syncope and advanced structural heart disease where thorough invasive and noninvasive investigations have failed to define a cause
4. Familial cardiomyopathy associated with sudden death
5. LV noncompaction

TABLE 23.2 Indications for Implantable Cardioverter–Defibrillator Therapy (Continued)

6. Recurrent syncope associated with complex congenital heart disease and advanced systemic ventricular dysfunction when thorough invasive and noninvasive investigations have failed to define a cause

Class III

1. Patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 y
2. Incessant VT or VF
3. Patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up
4. NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D
5. Syncope of undetermined cause without inducible ventricular tachyarrhythmias and without structural heart disease
6. VF or VT that is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, RV or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease)
7. Ventricular tachyarrhythmias due to a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma)

VF, ventricular fibrillation; VT, ventricular tachycardia; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; DCM, Dilated cardiomyopathy; SCD, sudden cardiac death; ARVD/C, arrhythmogenic right ventricular dysplasia/cardiomyopathy; CRT-D, cardiac resynchronization therapy with a defibrillator; RV, right ventricle; LV, left ventricle.

Adapted from the 2008 ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities.

to SCD, such as HCM, ARVD, Brugada syndrome, and LQTS, and an ICD is also indicated in select patients. The bradyarrhythmias respond well to pacemaker therapy. Radiofrequency catheter ablation is the therapy of first choice in patients with WPW syndrome and is an effective synergistic therapy in patients with VT who have recurrent ICD shocks.

Evidence from several recent randomized trials demonstrates the superiority of the ICD over antiarrhythmic drugs for the population requiring secondary prophylaxis. Antiarrhythmic drugs such as amiodarone, sotalol, and mexiletine may be of use in those patients who experience frequent ICD shocks.

V. PROGNOSIS

A. VF and pulseless VT ("shockable rhythms") are the initial rhythm in approximately one-quarter of SCA victims and are associated with more favorable outcomes than asystole or PEA. VT/VF incidence declines by ~10% with each minute since the onset of SCA; therefore, witnessed SCA and prompt recognition and defibrillation are associated with improved survival. Only one-third of SCA victims receive bystander CPR. A recent large study of cardiac arrest incidence and outcomes in North America found that of the 58% of patients in whom resuscitation was attempted, 7.6% survived to hospital discharge, with wide regional

variation. This proportion rose to 21% if the initial rhythm was VF. A number of factors have been identified to aid prognostication post arrest, including preexisting comorbidities, absent pupillary and corneal reflexes, extensor or no motor response to pain on day 3, and myoclonus status epilepticus; however, none are definitive.

VI. FUTURE. Large population studies are needed to better define the incidence of SCD across ethnic/racial groups and elucidate the mechanisms. Discovery of risk markers of SCD in the general population, such as clinical, molecular, and genetic factors, will facilitate targeting of evaluation and therapy to those who need it. Coronary artery disease and its consequences account for 80% of SCD, often occurring as the first presentation of CAD. Given the difficulty in identifying those with subclinical disease who are ostensibly at low risk, focus has recently moved to primordial prevention—the prevention of the development of risk factors for CAD. This will likely have the most impact on SCD at the population level, but its effects are difficult to measure. In those at established risk, improved risk markers that refine the current LVEF-based approach will allow better targeting of ICD therapy.

Atrial Fibrillation

I. INTRODUCTION. Atrial fibrillation (AF) is the most common sustained tachyarrhythmia and is associated with increased cardiovascular morbidity, mortality, and preventable stroke, accounting for approximately one-third of cardiac hospitalizations for cardiac rhythm disturbances. The incidence and prevalence of AF increase with age, with a prevalence of 0.4% to 1% in the general population and as high as 8% in patients older than 80 years. In addition, the age-adjusted incidence in the Framingham study has increased significantly from the 1960s to the present. It is estimated that 3 million people in America and 6 million people in Europe have either paroxysmal AF or persistent AF. AF is associated with increased risk of stroke, heart failure exacerbation, and all-cause mortality, especially in women. The mortality rate in patients with AF is about twice that of patients with normal sinus rhythm (NSR).

A. Classification. AF may be classified as lone, idiopathic, first detected, recurrent, paroxysmal, persistent, long-standing persistent, and permanent. **Lone AF** is used to describe patients experiencing AF without clinical or echocardiographic evidence of cardiopulmonary disease. **Idiopathic AF** refers to the uncertainty of AF origin without considering age or underlying cardiovascular pathology. During a patient's first detected episode of AF, it should be noted whether it is self-limited or the patient symptomatic with the arrhythmia. When a person has experienced two or more episodes of AF it is considered **recurrent**, and once recurrent AF is terminated it is referred to as **paroxysmal**. Paroxysmal episodes are usually self-terminating and, at least initially, do not usually require direct current cardioversion (DCC). **Persistent AF** usually lasts longer than 7 days and requires cardioversion for its termination. **Long-standing persistent** is when AF has lasted for > 1 year. AF becomes **permanent** once cardioversion, either electrical or chemical, is unsuccessful and presence of arrhythmia is accepted by the patient and physician and hence rhythm control interventions are not pursued.

B. Clinical presentation. As with all arrhythmias, the clinical presentation of AF can vary widely and **patients may be asymptomatic**, despite rapid rates of ventricular response. Common symptoms include **palpitations, fatigue, dyspnea and/or shortness of breath, dizziness, and diaphoresis**. Less commonly, patients may present with extreme manifestations of hemodynamic compromise, such as **chest pain, pulmonary edema, and syncope**. AF is often noted in patients presenting with a new thromboembolic stroke, with reported rates of 10% to 40%.

C. Differential diagnosis. AF needs to be distinguished from multifocal atrial tachycardia (MAT), frequent premature atrial contractions, and automatic atrial tachycardias.

D. Etiology. AF is most commonly associated with advanced age, hypertension, valvular heart disease, congestive heart failure (CHF), and coronary artery disease (CAD). The pathophysiology is dependent on the interaction between atrial anatomic and physiologic factors that favor the initiation and maintenance of the arrhythmia. Pathophysiologically, these entities result in left atrial fibrosis, pulmonary vein dilation, and reduced atrial contractility, which in turn result at a cellular

level in abnormal intracellular calcium handling, atrial myolysis, connexin down-regulation, and altered sympathetic innervation. Structural remodeling results in electrical dissociation between muscle bundles and local conduction heterogeneities facilitating the initiation and perpetuation of AF. This electroanatomical substrate permits multiple small reentrant circuits that can stabilize the arrhythmia and lead to the establishment of AF.

AF has been associated with physiologic stress, drugs, pulmonary embolism, chronic lung disease, hyperthyroidism, caffeine, infectious processes, and various metabolic disturbances. AF has also been linked with obesity and likely underlying sleep-disordered breathing. This phenomenon seems to be mediated by left atrial dilation. Other less common cardiac associations include Wolff-Parkinson-White (WPW) syndrome, pericarditis, and cardiomyopathy. Surgery, particularly **cardiac surgery, is associated with a high risk of postoperative AF** that depends on the type of cardiac surgery and is highest for mitral valve surgery, which may reach 35% to 50%. Persistence of AF has been correlated with elevated C-reactive protein levels, which raises the question of a role for inflammation in this condition, and atrial natriuretic peptide has been found to be elevated in people with acute AF. This hormone, which is released by myocardial tissue in response to increased wall stress, promotes diuresis and vasodilation. However, with long-standing AF, atrial natriuretic peptide levels remain within the normal range and patients do not experience its useful hemodynamic effects.

E. Pathophysiology

1. The role of the pulmonary veins as a source of triggers and/or drivers in AF is increasingly appreciated. A previous model proposed by Moe et al. in 1962 had described multiple reentrant wavelets within the atrial tissue (substrate) that contributed to the maintenance of AF. Recent data support **a focal mechanism involving both increased automaticity and multiple reentrant wavelets, occurring predominantly in the left atrium around the pulmonary veins**. A new model incorporates these mechanisms of initiators/drivers of AF and atrial substrate conditions for AF maintenance. This in turn may be affected by various modulating factors, such as autonomic tone, medications, atrial pressure, and catecholamine levels. AF is a very complex arrhythmia, and this mechanistic model simply serves to provide a conceptual framework from which to gain insight into it.
2. Paroxysmal, persistent, or chronic AF presents a **considerable risk for thromboembolism;** lone AF is presently thought to also increase the risk, but to a lesser extent. **The risk of stroke becomes more pronounced with increased age.** An increased risk of stroke has been shown to be associated with AF in the presence of any of the following: **age > 65 years, history of diabetes, history of hypertension, history of CHF, history of prior stroke, or transient ischemic attacks (TIAs)**. Left ventricular (LV) systolic dysfunction predicts ischemic stroke in patients with AF who do not receive antithrombotic therapy.

F. Laboratory examination and diagnostic testing. The initial evaluation of a patient with new-onset AF includes at a minimum a detailed history including enquiry about family history of AF and physical examination to define the clinical type of AF—frequency, duration, and precipitating factors—and to delineate the presence and nature of symptoms associated with AF. In addition, evaluation should include the following:

1. **A 12-lead electrocardiogram** (ECG) to identify the rhythm (that is to verify AF), underlying LV hypertrophy, and presence of preexcitation, and to diagnose the existence of CAD and any other atrial arrhythmias. A 12-lead ECG may also be used to measure and follow PR, QRS, and QT intervals during the treatment with antiarrhythmic agents. In AF the P waves are absent. Atrial activity is chaotic and fibrillatory **(F) waves are present**. The baseline of the ECG is often

undulating and may occasionally have coarse, irregular activity that can resemble atrial flutter, but it is not as stereotypical from wave to wave as atrial flutter. AF is distinguished from MAT by the presence in MAT of at least three different morphologic types of P waves. **Ventricular rhythm is usually irregularly irregular, and if AF is suspected with a regular ventricular response, then heart block with a junctional or ventricular escape should be considered**. The **atrial rate** is generally in the **range of 400 to 700 beats/min,** while the ventricular response is generally in the range of 120 to 180 beats/min in the absence of drug therapy. Ventricular response may be 180 beats/min or greater in the presence of an accessory pathway.

2. **Transthoracic echocardiogram** is usually performed to identify the presence of valvular heart disease, to assess atrial and ventricular size and function, and to document coexistent pulmonary hypertension. Echocardiography is also used as a prognostic tool to predict the development of systemic complications from AF and to help in the decision to initiate antithrombotic therapy. **Echocardiographic predictors of increased thromboembolic risk include mitral stenosis, left atrial enlargement, reduced LV systolic function, decreased left atrial appendage emptying velocities, and evidence of spontaneous contrast ("smoke") or thrombus in the left atrium or left atrial appendage**.
3. **Tests of thyroid, renal, and hepatic function.** Hyperthyroidism should always be considered, especially when the ventricular rate is difficult to control.
4. Additional investigation in selected patients with AF may include ambulatory ECG monitoring (e.g., Holter), or a 6-minute treadmill walk test to document heart rate response to exercise and an evaluation of sleep-disordered breathing should be considered especially in obese patients.

G. Therapy. The therapy of choice in any unstable patient where AF is recent in onset and contributing to the instability is immediate DCC. The term "unstable" should include the patient who is highly symptomatic (e.g., chest pain and pulmonary edema), as well as the patient who is hemodynamically unstable. **General management of AF centers on three areas: control of the ventricular response, minimization of the thromboembolic risk, and restoration and maintenance of sinus rhythm**.

1. **Control of the ventricular response.** The ventricular response is generally **controlled through drugs** that slow conduction through the atrioventricular (AV) node. AF that presents in the setting of WPW syndrome usually has evidence of preexcitation on ECG and is treated differently from AF conducting down the AV node alone. As noted previously, **intravenous calcium channel blockers, β-blockers, adenosine, and lidocaine are contraindicated in patients with AF and WPW syndrome associated with preexcitation because they facilitate conduction down the accessory pathway, causing acceleration of the ventricular rate, hypotension, and ventricular fibrillation**. In the hemodynamically stable patient, class I antiarrhythmic medications such as procainamide may be administered intravenously, which diminishes antegrade conduction down the accessory pathway and decreases the degree of preexcitation and may convert the AF. For patients without evidence of preexcitation, the following agents are available to control the ventricular rate.
   a. β-Blockers have a **rapid onset of action,** as well as **short half-lives in both the oral and intravenous forms.** These medications should be used cautiously in patients who have known decreased systolic function or evidence of heart failure. Intravenous preparations of metoprolol, esmolol, and propranolol have their onset of action in approximately 5 minutes. Orally available β-blockers of varying durations of action can be used for rate control. These include metoprolol and propranolol, as well as atenolol, nadolol, and a number of less commonly used agents. Amiodarone is an antiarrhythmic

medication with β-blocking properties and can be used for both rate and rhythm control in the acute setting. Sotalol is another class III antiarrhythmic medication with β-blocking properties, which can be used for both rate and rhythm control; however, this medication is available in oral form only and is more proarrhythmic than amiodarone.

b. Calcium channel blockers such as diltiazem and verapamil are available in both intravenous and oral forms. The intravenous forms are rapidly effective and have a short duration of effect. **In appropriate patients, they provide rapid control of the ventricular response**. Both oral diltiazem and verapamil are available in short-acting and sustained-release preparations.

c. Digitalis has long been used for rate control. Given its relatively long onset of action, **digoxin is ideally used in patients with decreased LV function or where a contraindication exists to the use of β-blockers or calcium channel blockers** (e.g., bronchospastic airway disease, asthma, or hemodynamic instability). It may be used as an adjunct to β-blockers or calcium channel blockers in patients in whom these medicines alone do not provide sufficient control of the heart rate. Digoxin is usually **effective at controlling the resting heart rate;** however, it is **less effective at lowering the ventricular response to activity**. Because of this it is recommended that if digoxin alone is used in rate control, the patient should undergo monitored exercise and the exertional heart rate verified to be < 110 beats/min.

Digoxin can be administered intravenously or orally. The **onset of action of digoxin is slow** (1 to 4 hours). Initially dosing of digoxin is 0.25 mg intravenously every 6 hours for a total of 1 mg every 24 hours. Then a maintenance dose is given, which is based on the patient's renal function. Digoxin is **generally well tolerated, although it is associated with adverse effects**, such as gastrointestinal toxicity and neurotoxicity, and because of its long half-life (38 to 48 hours) is more likely to be associated with symptomatic bradycardia requiring intervention such as temporary pacing.

d. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor antagonists may decrease the incidence of AF by decreasing left atrial pressure and by reducing the frequency of atrial premature beats. These medications may also reduce atrial fibrosis and decrease the recurrence of AF. Withdrawal from ACE inhibitors is associated with postoperative AF in patients undergoing coronary artery bypass grafting (CABG) surgery, and concurrent therapy with ACE inhibitors and antiarrhythmic agents enhances the maintenance of sinus rhythm.

e. HMG-CoA reductase inhibitors: statin drugs decrease the risk of AF recurrence following cardioversion. The mechanisms underlying this are poorly understood but probably include an inhibitory effect on the progression of coronary disease as well as their pleiotropic anti-inflammatory and antioxidant properties.

f. Antiarrhythmic agents such as dofetilide and ibutilide are effective for conversion of atrial flutter and AF but are not effective for the control of ventricular rate alone. Propafenone, which is a class IC antiarrhythmic drug, exerts additional mild β-blocking effects and may slow conduction across the AV node, although this is seldom sufficient to control the rate in patients with AF and may paradoxically cause an increase in AV nodal conduction and accelerate the ventricular rate response. Flecainide is another class IC agent that is very effective in converting AF in structurally normal hearts but like propafenone requires concomitant AV nodal blockage.

2. Thromboembolic risk management

a. Current recommendations regarding the use of antithrombotic therapy to prevent the development of thromboembolism in patients with AF are to

use antithrombotic therapy in all patients with AF except those with lone AF or with contraindications to antithrombotic agents. **Lone AF is defined as that occurring in a structurally normal heart, in a patient younger than 65 years.** The American Heart Association (AHA) recommends that the individualized selection of appropriate antithrombotic agents **associated with the highest risk of stroke in patients with AF include a history of prior thromboembolism (stroke, TIA, and systemic embolism) and rheumatic mitral stenosis.** Moderate risk factors for stroke include age older than 65 years, CAD, CHF, female gender, hypertension, diabetes mellitus, and renal insufficiency. Presence of more than one moderate risk factor suggests the use of a vitamin K antagonist with a goal international normalized ratio (INR) of 2.0 to 3.0 or or alternative anticoagulation with dabigatran, rivaroxaban or apixaban. Aspirin in doses of 81 to 325 mg daily is recommended as an alternative to vitamin K antagonism in low-risk patients or in those with contraindications to oral anticoagulation, and more recent evidence suggests that combination of aspirin and clopidogrel is superior to the use of either agent alone in patients who are unable to tolerate warfarin therapy. The guidelines also suggest similar use of antithrombotic therapy in patients with atrial flutter. Table 24.1 outlines one method of selecting the appropriate antithrombotic therapy for any given patient.

Based on the multivariate analysis from randomized controlled trials (RCTs), there have been several clinical scores developed to stratify the risk of systemic complications. The most well known of these is called the **CHADS** (*C*ardiac Failure, *H*ypertension, *A*ge, *D*iabetes, and *S*troke) risk index, which is a point system and assigns two points for history of TIA or stroke and one point for

TABLE 24.1 Selection of Appropriate Antithrombotic Therapy

Risk category	Recommended therapy	
No risk factors	Aspirin, 81–325 mg daily	
One moderate risk factor	Aspirin, 81–325 mg daily or warfarin (INR 2.0–3.0, target 2.5)	
Any high risk factor or more than one moderate risk factor	Warfarin (INR 2.0–3.0, target 2.5)[a]	
Less validated or weaker risk factors	**Moderate risk factors**	**High risk factors**
Gender (female)	Age ≥ 75 y	Previous stroke, TIA, or embolism
Age (65–74 y)	Hypertension	Mitral stenosis
Coronary artery disease	Heart failure	Prosthetic heart valve[b]
Thyrotoxicosis	LV ejection fraction 35% or less	
	Diabetes mellitus	

[a]If mechanical valve, target INR > 2.5.
[b]Mechanical prosethetic heart valve especially if in the mitral position to replace "prosthetic heart valve"
INR, international normalized ratio; LV, left ventricular; and TIA, transient ischemic attack.
Adapted from ACC/AHA practice guidelines.

each of the following risk factors: age older than 75 years, hypertension, diabetes, or recent heart failure. This risk factor index was evaluated retrospectively in patients older than 65 years and with nonvalvular AF, and the stroke risk varied from 1.8% per year in the lowest risk group with a CHADS score of 0, to 18.2% per year for those with an index score of 6. Another thromboembolic risk factor scoring system is the CHA2DS2-VASc, which assigns two points for age > 75 years and prior history of TIA or stroke and one point for each of the *following* risk factors: CHF, hypertension, diabetes, stroke, vascular disease, age 65 to 74 years, and female gender. Thus, this risk stratification scheme extends the CHADS2 scheme by considering additional stroke risk factors that may influence the decision on whether or not to anticoagulate with a threshold for therapy that is similar to the CHADS scheme. An assessment of bleeding risk is an integral part of patient evaluation prior to initiating anticoagulation. A simple bleeding risk score (HAS-BLED: hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile INR, elderly [age > 65 years], drugs/alcohol concomitantly) has been used to assess the risk of bleeding while on anticoagulant therapy. A score of ≥ 3 indicates higher risk and suggests caution and regular review of the patient following the initiation of anticoagulant therapy.

Following cardioversion, therapeutic anticoagulation should be continued until sinus rhythm has been maintained for at least 4 weeks to allow for recovery of the atrial transport mechanism and for the recurrence of AF. The decision to anticoagulate beyond 4 weeks will be dependent on the CHADS2 score of the patient with long-term anticoagulation being recommended for all patients with a CHADS2 score ≥ 2. For patients with a CHADS2 score of 1, the physician and patient should discuss the merits and risks of long-term anticoagulation versus the use of aspirin alone. **If cardioversion cannot be postponed for 3 weeks and the AF has been present for > 48 hours, patients should be anticoagulated (Table 24.2) with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin as a bridge to therapeutic INR or alternatively dabigatran, rivaroxaban or apixaban could be used and the patient should undergo transesophageal echocardiography (TEE)** to rule out atrial thrombus; **then anticoagulation should be** used for at least 4 weeks after cardioversion.

b. A number of major trials have attempted to compare the benefits of aspirin and warfarin in minimizing the stroke risk in patients with AF. Overall, warfarin has shown an annual average reduction of 68% in relative risk for stroke, with aspirin showing a reduction anywhere from 0% to 44% (mean, ~30%). A recent trial has shown that clopidogrel reduces the risk of embolic stroke similar to that of aspirin and the combination of aspirin and clopidogrel is superior to either agent alone but inferior to warfarin therapy.

The decision to anticoagulate patients with AF depends on both the risk of thromboembolic complications and the risk of bleeding. In younger patients at low risk for stroke (younger than 65 years, without other risk factors), and who generally lead active lifestyles that place them at increased risk for bleeding, **aspirin** may be an acceptable alternative to warfarin. **Older patients at greater risk for stroke (age 65 and older, with or without other risk factors)** should be anticoagulated with **warfarin to maintain an INR of 2 to 3 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban. The risk of thromboembolism increases rapidly at INR levels even slightly < 2, and the risk of bleeding increases at INR levels > 3**. Studies of fixed low-dose warfarin and aspirin have shown ineffective protection from thromboembolic risk as compared with anticoagulation with warfarin to maintain an INR of 2 to 3, and thus are not recommended. **Patients who have contraindications to warfarin** therapy should be treated with **aspirin or the combination of aspirin and clopidogrel should be considered if the patients can tolerate it**.

TABLE 24.2 Anticoagulation Strategies in Patients Who Require Cardioversion

Length of time in atrial fibrillation	Elective cardioversion?	Timing and anticoagulation strategy
< 48 h	Yes	Depends on the presence of risk factors for thromboembolism
< 48 h	No	Immediate DCC may be performed without delay or need to start anticoagulation
> 48 h or unknown	Yes	A goal INR 2.0–3.0 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban for at least 3 weeks prior to and 4 weeks following DCC
> 48 h or unknown	Yes	A TEE can be performed while the patient is on IV heparin with a goal aPTT ratio of 1.5–2.0, and if no identifiable thrombus is present, DCC can safely be performed, followed by 4 weeks of oral coumadin with goal INR of 2.0–3.0 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban
> 48 h or unknown	Yes	If the TEE demonstrates a thrombus, then anticoagulation with coumadin with a goal INR of 2.0–3.0 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban for a period of 3 weeks prior to a repeat TEE to assess for thrombus resolution. If no identifiable thrombus is visible on repeat TEE, then DCC should be followed by at least 4 weeks of anticoagulation with INR of 2.0–3.0 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban post DCC

DCC, direct current cardioversion; INR, international normalized ratio; TEE, transesophageal echocardiography; IV, intravenous.

The **risk of thromboembolism increases with longer duration of AF. Current guidelines recommend that patients who have been in AF for longer than 48 hours should be systemically anticoagulated** whenever possible. This can be accomplished quickly with intravenous unfractionated heparin, subcutaneous low-molecular-weight heparin, or oral dabigatran, rivaroxaban or apixaban. Cardioversion should be delayed in patients with AF of > 48 hours duration who have not been anticoagulated as described in the AHA guidelines discussed previously unless a patient is sufficiently unstable that more rapid cardioversion is necessary, in which case screening of the atria for the presence of thrombus with TEE is appropriate.

c. TEE is highly effective in the detection of thrombus in the atria and in the left atrial appendage and is more sensitive in this regard than transthoracic echocardiography. The Assessment of Cardioversion using Transesophageal

Echocardiogram (ACUTE) study compared the use of TEE screening of patients with AF prior to cardioversion with a conventional approach based on 3 weeks of anticoagulation therapy. In the TEE group, those patients without thrombus on TEE underwent immediate cardioversion after therapeutic anticoagulation had been initiated and without waiting for 3 weeks. Patients were continued on warfarin for 4 weeks after the cardioversion as in the conventional group. No significant difference was noted in the embolic event rate or in the likelihood of maintenance of normal rhythm. TEE cardioversion is now considered an acceptable alternative when the conventional approach is not possible.

d. Cardiac output may be decreased after cardioversion in up to one-third of patients, and this can persist for as long as a week. Rarely, this leads to pulmonary edema as soon as 3 hours after cardioversion. Atrial function also declines immediately after cardioversion, even after that occurring spontaneously or pharmacologically. Cardiac output should return to baseline within 4 weeks. The risk of thromboembolism is thus still increased during this time period, and that is why systemic anticoagulation is recommended for a minimum of 4 weeks after cardioversion.

e. After 4 weeks of therapy, the decision to continue anticoagulation is based on each patient's individual risk for recurrence of AF. **Patients who cannot be successfully cardioverted should be anticoagulated long-term**, as should patients with frequent recurrences/paroxysms.

f. In addition to the expanding number of pharmacologic options for anticoagulation, there are now nonpharmacologic methods for reducing thromboembolic risk. In the Embolic Protection in Patients with Atrial Fibrillation Trial (PROTECT trial), the WATCHMAN left atrial appendage occlusion system was noninferior to anticoagulation with warfarin in terms of thromboembolic outcomes. More data are needed on the long term safety and efficacy of this device.

3. Rate control during AF. Patients with AF may have controlled heart rates at rest, but they accelerate even with mild exercise. Hence, it is useful in patients with chronic AF to evaluate the heart rate response to submaximal or maximal exercise or to monitor the heart rate over an extended period (such as a 24-hour Holter monitor). The traditional criteria defining that adequate rate control varies with age but usually involves achieving a ventricular rate between 60 and 80 beats/min at rest and between 90 and 110 beats/min during moderate exercise have not been shown to be beneficial over a more lenient approach to achieve a resting heart rate of < 110 beats/min in patients with persistent or continuous AF and stable LV systolic function.

4. Restoration and maintenance of sinus rhythm. There is debate whether restoration to sinus rhythm is beneficial for patients whose disease is asymptomatic as compared with a combined strategy of simply controlling the ventricular response and minimizing the thromboembolic risk. Data from nonrandomized trials show an increase in mortality in patients on long-term antiarrhythmic therapy for AF. The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial compared two treatment strategies in patients with asymptomatic or tolerable AF. One group was treated with antiarrhythmic drugs and cardioversion as necessary to maintain sinus rhythm. The other group was allowed to remain in AF and the ventricular rate alone was controlled. Both groups received anticoagulation therapy. There was no difference in survival or embolic event rate between the two groups.

a. Direct current cardioversion. When restoration of sinus rhythm is deemed necessary, this is most effectively carried out with DCC. **DCC is successful at least 80% of the time**, whereas pharmacologic rates of successful cardioversion are lower and depend on the antiarrhythmic drug used and the clinical scenario. Whenever possible, **DCC should be carried out under sedation, with appropriate cardiac and hemodynamic monitoring, and**

in the presence of personnel skilled in airway control/management. See Chapter 59 for details of DCC, including sedation and methods.

b. Pharmacologic cardioversion

(1) The "drugs first" approach may promote more successful DCC and/or maintenance of sinus rhythm after DCC, if the attempt at pharmacologic cardioversion is unsuccessful. Similarly, it is reasonable to **attempt chemical cardioversion on any patient who fails DCC**, especially before repeated attempts at DCC.

(2) Table 24.3 shows the currently available intravenous agents available for the pharmacologic cardioversion of AF to sinus rhythm.

(i) Procainamide is a class IA antiarrhythmic drug that is often considered **the first line of therapy** for the pharmacologic conversion of AF occurring in the postoperative period after cardiac surgery.

TABLE 24.3 Intravenous Medications Used for the Cardioversion of Atrial Fibrillation

Drug name	Vaughan Williams class	Dose	Adverse side effects
Amiodarone	III	5–7 mg/kg over 30–60 min, followed by 1.2–1.8 g/d until 10 g, then 200–400 mg daily for maintenance	Hypotension, bradycardia, hyperthyroidism, hepatitis, skin discoloration, and phlebitis
Ibutilide	III	1 mg over 10 min, repeat as needed	Torsade de pointes, increased QTc
Propafenone	IC	1.5–2.0 mg/kg over 20 min	Hypotension and atrial flutter with RVR
Flecainide	IC	1.5–3.0 mg/kg over 10–20 min	Hypotension and atrial flutter with RVR
Vernakalant (approved in Europe but not yet in United States)	III	3 mg/kg IV infusion over 10 min. Second infusion of 2 mg/kg IV over 10 min after 15 min of rest	Vernakalant is contraindicated in patients with systolic blood pressure < 100 mm Hg, severe aortic stenosis, heart failure (NYHA classes III and IV), ACS within the previous 30 d, or QT interval prolongation. Before its use, the patients should be adequately hydrated. ECG and hemodynamic monitoring should be used, and the infusion can be followed by DCC if necessary. The drug is not contraindicated in patients with stable coronary artery disease, hypertensive heart disease, or mild heart failure

RVR, rapid ventricular response; ACS, acute coronary syndrome; ECG, electrocardiogram; DCC, direct current cardioversion.

(ii) Amiodarone is considered a class III antiarrhythmic drug, although it has properties of all of the four Vaughan Williams classes. Like procainamide, amiodarone is commonly used intravenously in the postoperative period for AF after cardiac surgery, particularly for those patients with renal insufficiency or failure who are not candidates for procainamide.

(iii) Ibutilide is an agent approved for the pharmacologic conversion of AF. The incidence of torsade de pointes is at least 1% to 2% with ibutilide, which is higher than that seen with procainamide or amiodarone. Ibutilide is available only in the intravenous form and is, therefore, not an option for long-term maintenance of sinus rhythm.

(iv) Vernakalant is an agent that was recently approved in Europe for chemical cardioversion but has not yet been approved by the US Food and Drug Administration (FDA). It is more effective than amiodarone for conversion of AF to sinus rhythm. Vernakalant is contraindicated in patients with systolic blood pressure < 100 mm Hg, severe aortic stenosis, heart failure (NYHA classes III and IV), acute coronary syndrome (ACS) within the previous 30 days, or QT interval prolongation. Before its use, patients should be adequately hydrated. ECG and hemodynamic monitoring are mandatory, and the infusion can be followed by DCC if necessary. The drug is not contraindicated in patients with stable CAD, hypertensive heart disease, or mild heart failure. The clinical positioning of this drug has not yet been determined, but it is likely to be used for acute termination of recent-onset AF in patients with lone AF or AF associated with hypertension, CAD, or mild to moderate (NYHA classes I and II) heart failure.

(3) A number of **oral agents** are available for the pharmacologic cardioversion of AF. **In appropriate patients the class IC agents, such as flecainide and propafenone, may be particularly effective for pharmacologic cardioversion**. In the text to follow are mentioned some other agents that may be used in the long-term for maintenance of sinus rhythm in patients with AF. It should be kept in mind that initiation or upward dose titration of antiarrhythmic drugs should be done with caution and, in many instances, should be performed in a hospital setting with a cardiac monitor. This is particularly true for the class III agents sotalol and dofetilide. On the other hand, in patients without structural heart disease, the class IC agents flecainide and propafenone may be considered for initiation on an outpatient basis. Table 24.4 outlines the presently available orally acting medications to treat AF.

(i) Class IA agents. These agents have seen a decline in their use, primarily due to a high incidence of intolerance because of side effects but also due to evidence of possible increased mortality for those patients with structural heart disease.

- **Procainamide.** This medication has not been used as frequently now for long-term treatment of AF, especially due to the potential for gastrointestinal, hematologic, and immunologic (e.g., lupus-like syndrome) side effects. An active metabolite of this drug, *n*-acetylprocainamide (NAPA), is cleared renally and has class III antiarrhythmic properties. Blood levels of both procainamide and NAPA need to be monitored to prevent toxicity, especially in the setting of renal and/or hepatic insufficiency.
- **Quinidine** is another class IA drug that has not been used as frequently in recent years, again primarily due to a relatively high

TABLE 24.4 Oral Agents Available for Rhythm Control in Atrial Fibrillation

Drug name	Vaughan Williams class	Cardioversion dose		Daily maintenance dose
Amiodarone	III	400–800 tid dosing daily until 10 g, then		200–400 mg
Dofetilide	III	Based on CrCl (mL/min):	Dose: (μg bid)	Same. Dosing also adjusted for adjusted QTc
		> 60 mL/min	500	
		40–60	250	
		20–40	125	
		< 20	Contraindicated	
Propafenone	IC	600 mg		450–900 mg
Flecainide	IC	200–300 mg		Same
Sotalol	III	160–320 mg		Same
Dronedarone	III		Contraindicated if CrCl < 30 and patient with class IV heart failure, admission for CHF in preceding 4 weeks especially if EF < 35%	400 mg bid

CHF, congestive heart failure; EF, ejection fraction; IV, intravenous.

incidence of gastrointestinal, hematologic, and neurologic side effects. In addition, quinidine interacts with several cardiac and noncardiac medications.

- **Disopyramide.** This antiarrhythmic medication may have a "niche" for the treatment of vagally mediated AF or AF that occurs in the setting of hypertrophic cardiomyopathy. However, its **negative inotropic effects** are greater than those of other class IA drugs, and it is associated with **greater anticholinergic effects** such as constipation and urinary retention.

(ii) Class IC agents. This group has become the preferred antiarrhythmic drugs for the management of AF in patients without structural heart disease, especially those patients with "lone" AF. These medications should not be used in patients with structural heart disease, especially patients with known or suspected ischemic heart disease. **Flecainide** was shown in the Cardiac Arrhythmia Suppression Trial (CAST) to be associated with increased mortality when used for suppression of ventricular arrhythmias in patients with LV dysfunction

following myocardial infarction (MI). This has led to much concern over the use of the class IC agents in any patient with CAD and even in other types of structural heart disease.

- **Flecainide.** This is a well-tolerated medication that has a low incidence of neurologic side effects. This medication is approved in both oral and intravenous forms for the acute cardioversion of AF. Randomized trials with this drug show that it converts 60% to 70% of patients with new-onset AF at 4 hours and close to 90% at 8 hours. Oral administration and intravenous administration were equally efficacious, but the average response to the intravenous loading is seen within 1 hour, whereas it is 3 hours with the oral loading dose.
- **Propafenone.** This is also a well-tolerated medication. Its β-blocking properties limit its use in patients intolerant of such medications. Like sotalol, this property allows for its use as a single agent for AF suppression and ventricular rate control.

(iii) Class III agents. This group has become the preferred treatment for AF in patients with structural heart disease.

- Sotalol also has β-blocking properties, which makes it useful as a **single-agent therapy** for AF suppression and ventricular rate control. However, these properties are also responsible for the intolerance seen with this drug and may contribute to exacerbation of heart failure in some patients. **The dose must be reduced with renal insufficiency**.
- **Dofetilide.** This is the latest antiarrhythmic drug to be approved by the FDA for management of AF. This drug is generally well tolerated and has been shown to be safe for patients with structural heart disease, in particular those patients who have had an MI and those with CHF. **This drug has been associated with proarrhythmia, especially in the setting of renal dysfunction. The prescription of the drug is tightly controlled, and only those certified in its use may prescribe it**.
- **Amiodarone.** This is a unique medication in that it has properties of all four Vaughan Williams classes. It is also unique with regard to its very long elimination half-life (up to 120 days). Amiodarone is effective for the management of AF but is generally reserved for patients in whom other antiarrhythmic drugs have been ineffective or poorly tolerated, due to the important potential organ toxicities that may occur, predominantly in the liver, lungs, thyroid, and eyes. It is recommended that patients treated with amiodarone have baseline and then regular screening tests such as ophthalmologic examination, pulmonary function study, chest x-ray, and blood tests for liver and thyroid function.
- **Dronedarone** is a multichannel blocker that inhibits the sodium, potassium, and calcium channels and has noncompetitive antiadrenergic activity. It is **similar to amiodarone with a much better side-effect profile, though it is less effective than amiodarone**. Contraindicated in NYHA classes III and IV or unstable heart failure, during concomitant therapy with QT-prolonging drugs, powerful CYP3A4 inhibitors, and creatinine clearance < 30 mg/mL. There is potential for serious liver toxicity with dronedarone and liver function tests have to be monitored closely when patients are on this medication.
- **Azimilide.** New class III antiarrhythmic drug that is not yet FDA approved for the management of AF.

(4) Figure 24.1, adapted from American Heart Association/American College of Cardiology/European Society of Cardiology (AHA/ACC/ESC) guidelines, outlines strategies used in the maintenance of sinus rhythm.

c. AV nodal ablation in conjunction with permanent pacemaker.

(1) Symptomatic refractory AF, especially when the ventricular rate is uncontrollable or such control is limited by underlying bradycardia, may be amenable to ablation of the AV node and implantation of a **rate-responsive single-chamber permanent pacemaker**. These patients still require systemic anticoagulation. A recent meta-analysis of 21 studies that included 1,100 patients who underwent AV nodal ablation for highly symptomatic AF concluded that AV nodal ablation and subsequent pacemaker implantation significantly improved the quality of life, exercise capacity, and LV function and decreased symptoms of AF. In a small subset of 56 patients who had impaired LV function (an ejection fraction < 40%) and AV nodal ablation, permanent pacemaker implantation caused an average improvement in ejection fraction of 8% and complete normalization of the ejection fraction in one-third of the patients. The remaining patients with persistent LV dysfunction after AV nodal ablation had a 5-year survival rate of <40%. The 1-year mortality rate after AV nodal ablation and permanent pacemaker implantation is approximately 6.3%, which includes a high 2% risk of sudden cardiac death (SCD), which is thought to be related to early post pacemaker implantation R-on-T phenomenon caused by pacemaker-induced bradycardia. For this reason, it has been suggested, without a great deal of support in the published literature, that pacemakers be programmed with a minimum heart rate of 90 beats/min for the first month after the AV nodal ablation procedure.

(2) Indications for permanent pacemaker for AF. A permanent pacemaker may be needed in patients who develop symptomatic bradycardia, which may be exacerbated by therapy for AF. This may occur because of an underlying sinus node dysfunction or perhaps poor AV conduction leading to slow ventricular rates during AF. Modern pacemakers have **"mode switching"** capabilities, so that the pacing mode changes from dual-chamber to single-chamber ventricular pacing at the onset of AF to avoid rapid ventricular pacing rates due to the pacemaker responding to the atrial activity.

(3) Limitations. Although, as mentioned earlier, AV nodal ablation has been shown to cause symptomatic improvement in patients with refractory and very symptomatic AF, its limitations include the potential lifelong need for anticoagulation, the loss of AV synchrony, and the lifelong pacemaker dependence with its attendant risks.

Several recent pacemaker trials have shown worsening hemodynamic effects of right ventricular (RV) apical pacing compared with biventricular pacing. The Post AV Nodal Ablation Evaluation (PAVE) trial randomized patients to RV apical pacing versus biventricular pacing following AV nodal ablation for permanent AF. At an average follow-up of 6 months, the biventricular-paced group had longer 6-minute walk times and increased peak oxygen consumption and reported improved quality of life. Although LV ejection fraction did not differ between the groups at baseline, at follow-up, the ejection fraction in the biventricular pacing group stabilized, whereas the ejection fraction in the RV apically paced group had declined significantly.

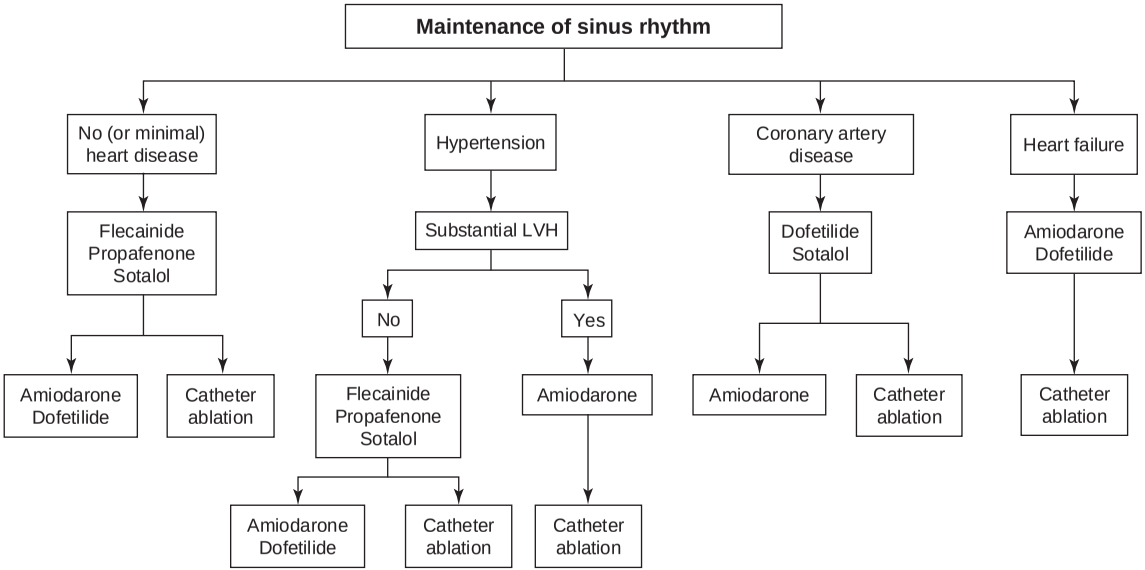

FIGURE 24.1 Therapeutic approach to the maintenance of sinus rhythm. Adapted from American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines. LVH, left ventricular hypertrophy.

Current recommendations regarding the choice of pacemaker following AV nodal ablation suggest the use of RV pacing devices in patients with normal LV function or in those thought to have reversible LV dysfunction secondary to AF with poor rate control. In patients with impaired LV function not caused by AF, a biventricular pacemaker with or without defibrillator capability should be considered. In patients who have undergone AV nodal ablation and developed heart failure symptoms following RV apical pacing, an upgrade from an RV apical system to biventricular system should be considered.

d. Implantable devices with treatment and suppressive strategies for AF are now available for selected patients. Some devices may terminate AF with a rapid atrial burst pacing or a cardioversion shock. Pacemakers that have pacing algorithms aimed at preventing AF episodes have become available. The use of such pacemakers in patients without an indication for pacing is still under investigation. A difficulty in their implementation is the frequency of episodes of AF in patients requiring device activation and the discomfort associated with shock delivery.

e. Invasive curative therapies. There are two major interventional approaches for the management or cure of AF, one based on a percutaneous approach and the other on a surgical approach. These approaches are not yet first-line therapy, but in recent years have become a much more attractive option for patients with troublesome AF in whom antiarrhythmic treatment has been ineffective or poorly tolerated.

(1) Catheter ablation of AF with pulmonary vein isolation (PVI). In 1998, Haissaguerre and colleagues described the presence of isolated foci in the left atrium and pulmonary veins and their role in the initiation of AF. They were also able to demonstrate that ablation of these foci could successfully terminate AF. Based on this early work, the field of AF ablation was born. Initial experiences with AF ablation attempted to mimic the surgical Maze procedure. Since that time, ablation has undergone various changes in both philosophy and technique.

Approaches to AF ablation can vary widely. Purely anatomic approaches may focus on the creation of linear lesions around the pulmonary veins and may not require demonstration of entrance or exit block. Other techniques focus on ablation of sites of autonomic ganglia or areas of complex fractionated electrograms. Electrogram-based approaches make use of a mapping catheter to help identify electrograms in areas targeted for isolation but may vary in the scope of the area targeted for isolation. Anatomic ablation techniques use recently developed three-dimensional (3D) mapping systems to demonstrate the anatomy of the left atrium and the pulmonary veins. Various anatomic techniques including the isolation of each of the four veins, individually or via isolation of two veins at a time, have been developed. In addition, anatomic lines extended to the mitral isthmus or involving the room of the left atrium have been utilized. Exit block is often used as an end point in the anatomic approach.

Electrogram-based techniques require the use of a second (ring) mapping catheter. After circumferential isolation, the mapping catheter is used to evaluate for the presence of gaps in the ablation line and these gaps are then ablated. There have also been experiences using electrogram-based approaches to perform additional ablation points in other areas of the heart, including the coronary sinus, the superior vena cava, and the right atrium, after performing PVI. Additionally, drug testing with adenosine and isoproterenol to provoke AF and thereby identify potential triggers for ablation is sometimes used.

Advances in techniques have improved the efficacy and safety of the procedure. One major advance has been the development of protocols that ablate outside the ostia of the pulmonary veins to help reduce the incidence of postprocedure pulmonary vein stenosis. Catheter ablation is now considered a reasonable alternative to pharmacologic therapy to prevent recurrent AF in symptomatic patients with little or no left atrium enlargement with a class I recommendation in the most recent guideline update. In addition, catheter ablation performed in experienced centers is useful in maintaining sinus rhythm in selected patients with significantly symptomatic, paroxysmal AF who have failed treatment with an antiarrhythmic drug and have normal or mildly dilated left atria, normal or mildly reduced LV function, and no severe pulmonary disease.

Patient preparation and procedural considerations. Prior to ablation, considerations including access, conscious sedation, and choice of anticoagulation regimen should be made on an individual patient basis. The presence of multiple catheters in the left atrium requires patients to be given full anticoagulation. Prior to the procedure, some centers require patients to be therapeutic on warfarin for 4 to 6 weeks. Patients not anticoagulated prior to the procedure should undergo transesophageal echocardiogram to exclude the presence of left atrial thrombus. Regardless of preprocedural anticoagulation status, patients are fully anticoagulated with unfractionated heparin during the procedure to achieve a prespecified targeted activated clotting time.

Catheters are placed in the right atrium and coronary sinus, typically via sheaths in the right and left femoral veins, and an additional sheath is often needed if intracardiac echo is used. The left atrium is accessed via transeptal puncture. Great care is needed, using fluoroscopic guidance to assure successful transeptal puncture, and many centers use intracardiac echo to assist in safely achieving transeptal puncture. After placement in the left atrium, circular "lasso" mapping and ablation catheters are used to approach the pulmonary veins. If used, intracardiac echo can assist 3D mapping techniques in identifying the pulmonary vein ostia.

End point for ablation differs depending on the technique used. On completion of electrogram-based ablation, success is demonstrated by the development of entry block in the antrum of the pulmonary veins. However, anatomic-based procedures do not require the demonstration of block.

Centers performing ablation should have backup available of physicians experienced in pericardiocentesis and cardiothoracic surgery, secondary to the development of hemorrhagic pericardial effusion or atrial appendage rupture.

The identification of the pulmonary veins as the predominant source of ectopic foci that trigger AF has led to catheter-based ablation strategies to electrically isolate the pulmonary veins by delivering radiofrequency energy at their ostium. In the initial series, foci of increased automaticity within the pulmonary veins were targeted and ablated. In one early series of 45 patients with AF, 62% became free of symptomatic AF over a mean follow-up of 8 months. However 70% of the patients required multiple procedures. In a subsequent study using the same approach, the success rate (defined as the absence of return of symptomatic AF) was 86% over a 6-month follow-up.

Continued research into the substrate for AF has demonstrated that there are many potentials that can contribute to the initiation and maintenance of AF and that these may arise in multiple areas of the right and left atria. Thus, catheter ablation procedures have been developed to

incorporate linear lesions in the roof of the left atrium and mitral valve isthmus ablation to account for these. Using this approach in a series of 70 patients with symptomatic AF, 70% of the patients were found to be free from AF following PVI without antiarrhythmic medications at 4 months of follow-up. The procedure continued to advance with the development of the circular mapping catheter, which allowed for more accurate mapping and isolation of the pulmonary veins.

At the time of this writing, the accumulated published experience in PVI suggests an approximately 70% to 90% success rate in patients with paroxysmal AF and 40% to 80% success rate in patients with persistent AF. It must be noted that the success rates in patients with depressed ejection fraction are much lower than that in patients with normal systolic function.

A newer approach to radiofrequency catheter ablation of AF involves the ablation of complex fractionated electrograms, which has a 91% efficacy reported at 1 year. This study also showed that restoration of sinus rhythm following catheter-based ablation of AF caused a significant improvement in exercise capacity, quality of life, and LV systolic function.

Presently, the long-term efficacy of catheter-based ablation is not known and requires further study. Long-term follow-ups from RCTs are presently either lacking in patient numbers or marred by high crossover rates or by antiarrhythmic use. The current ACC/AHA/HRS guidelines allow for the use of PVI in the treatment of symptomatic AF following intolerance to, depending on the substrate, at least one drug and as many as three antiarrhythmic drugs.

Complications. Major complications from catheter-based ablation have been reported in about 2% to 3% of patients and include pulmonary vein stenosis, systemic thromboembolism, atrial esophageal fistula, and the development of atypical left atrial flutter.

The incidence of **pulmonary vein stenosis** has diminished by the judicious use of radiofrequency ablation energy to target areas just outside the pulmonary veins so as to isolate the ostia of the pulmonary veins from the remainder of the left atrium. The use of intracardiac echocardiography to detect microbubble formation as a means to measure the magnitude of radiofrequency energy delivered has been reported to reduce the instance of pulmonary vein stenosis. This complication often presents as dyspnea and breathlessness in the weeks to months following catheter-based ablation, with radiographic evidence of asymmetric pulmonary edema or pulmonary emboli, as it results in obstructive venous outflow from a single pulmonary lobe. This diagnosis is best made by the use of computed tomography venography, but it can also be made through the use of TEE with the finding of high-velocity flow in the affected pulmonary vein.

Systemic embolic events, including embolic stroke, are among the most serious complications of catheter-based ablation of AF, and the reported incidence varies from 0% to 5%. A trial comparing heparin-dosing regimens found that increasing the intensity of anticoagulation reduces the probability of forming left atrial thrombi from 11% to 3%, when the activated clotting time was increased from 250 to > 3 00 seconds.

Atrial esophageal fistula is a relatively rare complication of PVI, and it is more likely to occur when extensive ablation occurs over the posterior left atrial wall where it abuts the esophagus. Typical symptoms include nausea, vomiting, fever, and sudden neurologic deterioration

(from systemic embolization), which occur in the days to weeks following ablation. Successful treatment of this condition requires prompt recognition of its clinical signs, as delay in the treatment often leads to death.

The development of **atypical left atrial flutter** is thought to be related to the development of scar in the left atrium, which creates the substrate for reentry required for this arrhythmia. The most important predictor of the development of left atrial flutter is the presence of an incomplete line of ablation, and it has been found that extending the ablation line to the mitral valve annulus may reduce the frequency of this complication. This arrhythmia, as is the case with right atrial flutter, is amenable to further catheter-based ablation.

(2) Cox-Maze procedure is a surgical approach that has been developed over the last 25 years and that tested the original hypothesis that reentry is the predominant mechanism for the development and maintenance of AF. It has undergone multiple revisions through the years, and now it has evolved to include techniques that surgically isolate the pulmonary veins and connect these dividing lines to the mitral valve annulus. The surgical procedure uses atrial incisions in critical locations to create barriers to the propagating wavelets that are responsible for the initiation and maintenance of AF and that consequently eliminate the macroreentrant circuits in the atrium necessary to maintain AF.

The Maze procedure has changed over the last two decades, and present techniques use transmural lesions to isolate the pulmonary veins and to connect these dividing lines to the mitral valve annulus, as well as lesions to create barriers in the right atrium. The reported success of the combined three developmental stages of the Cox-Maze procedure is 93% in patients with symptomatic AF who were intolerant of antiarrhythmic drugs. This long-term report included 178 patients, and there was a 2.2% risk of periprocedure death and a 6% risk of pacemaker requirement in the patients undergoing a Cox-Maze I procedure. Other, more current studies have reported lower success rate of around 70%. This procedure maintains the atrial transport function, and especially when allied with left atrial appendage ligation substantially reduces the risk of postoperative thromboembolic events.

Procedure risks include **death** risk, which is dependent on the patient's comorbidities but is usually estimated to be < 1% as an isolated procedure, the need for a **pacemaker**, **impaired atrial transport function**, and delayed **atrial arrhythmias** including atrial flutter.

The Maze procedure has not had widespread acceptance as a means of treatment for AF, except in patients undergoing open heart surgery. Even in these patients, the additional intraoperative time and complexity of the procedure have limited its widespread surgical application. Currently under development are less invasive approaches, including thoracoscopic and catheter-based epicardial techniques.

The Maze procedure is often associated with significant edema formation, probably due to atrial natriuretic peptide derangements. This is effectively mitigated by the use of aldosterone antagonists such as spironolactone for the first 4 to 6 weeks postoperatively. All procedures used to restore NSR in patients with AF have had a variable effect on the restoration of atrial transport function, depending on the duration of fibrillation before the procedure and the rhythm maintained following the procedure. The need for long-term anticoagulation therapy following these procedures is generally assessed on an individual basis.

II. SPECIAL CONSIDERATIONS

A. Postoperative AF. AF is common postoperatively. The incidence of AF postoperatively varies with the type of surgery and is highest following open heart surgery, during which time it ranges between 20% and 50%. It usually occurs in the first 5 days. Risk factors for perioperative AF include age, a history of AF, chronic obstructive pulmonary disease (COPD), valvular heart disease (especially mitral valve disease), atrial enlargement, perioperative heart failure, and withdrawal from a β-blocker or an ACE inhibitor. Postoperative AF is a major determinant of length of stay and thus of cost. It is associated with all the risks associated with AF in the nonpostoperative setting including hemodynamic compromise and thromboembolism.

1. **Therapy.** Postoperative AF is usually self-limited, and DCC is usually not needed. There are a variety of antiarrhythmic agents available for cardioversion in postoperative patients. In a small trial, ibutilide was found to be more effective than placebo for the treatment of postoperative AF. Sotalol is particularly acutely effective in patients with preserved LV systolic function, because the risk of proarrhythmic toxicity is small and also because its β-blocker action contributes to slowing the ventricular rate.

   AF carries an increased risk of stroke in post-CABG patients, and so anticoagulation with heparin followed by oral anticoagulants is recommended if AF persists for longer than 48 hours. The choice of antiarrhythmic therapy, choice of AV nodal blocking agents, and the use of either heparin and/or oral anticoagulants depend on the individual patient, the time from surgery, and the specific type of surgery.

2. **Prevention.** There is evidence supporting the prophylactic administration of β-blocker medications in patients undergoing cardiac surgery to prevent the development of AF. Sotalol has also been studied, but there is at present conflicting evidence regarding its effectiveness. Amiodarone, when given either prophylactically before cardiac surgery or following open heart surgery, has been found to significantly reduce the incidence of postoperative AF. In the Prophylactic Oral Amiodarone for the Prevention of Arrhythmias that Began Early After Revascularization (PAPABEAR) trial, oral amiodarone, dosed at 10 mg/kg beginning 6 days before and continuing for 6 days after surgery, decreased the incidence of postoperative AF by 50%. This efficacy was present in patients irrespective of whether CABG, valve surgery, or a combination was performed. Preoperative treatment with procainamide has yielded inconsistent results, as has treatment with either digoxin or verapamil.

   At present there are limited data supporting the use of atrial overdrive pacing as opposed to single-chamber pacing in the prevention of postoperative AF. In a randomized trial involving 132 patients undergoing CABG, postoperative biatrial pacing significantly reduced incidence of AF by 12.5% compared with left atrial pacing, right atrial pacing, or no pacing. A meta-analysis of 10 randomized trials also concluded that biatrial pacing, atrial pacing, and right atrial pacing reduced the incidence of AF after CABG surgery.

B. AF in acute MI. The incidence of AF following acute MI varies depending on the population sampled as well as the type of MI but ranges between 10% and 20% at 30 days. AF is more commonly associated with acute MI in older patients as well as those with a higher Killip class and more severe LV dysfunction. Patients with AF in the setting of an acute MI have a worse outcome at 30 days than those in sinus rhythm (29.3% with AF vs. 19% with NSR). Stroke rates are also increased in patients with post-MI AF.

The guidelines presently recommend urgent DCC in patients with acute MI who present with AF, especially if in rapid ventricular response with intractable ischemia or evidence of hemodynamic instability including CHF. Intravenous β-blockade is indicated for rate control to reduce myocardial oxygen consumption and demand, and digoxin is an alternative in patients with severe left surgical dysfunction and

heart failure. Anticoagulation is recommended in patients with large anterior MIs and those in which the AF becomes persistent. Post-MI ACE inhibitors seem to reduce the incidence of AF in patients with significant LV dysfunction. Post-MI use of carvedilol also seems to diminish the incidence of AF and atrial flutter.

C. AF and WPW syndrome. The most feared complication of the WPW syndrome is the development of ventricular fibrillation and SCD secondary to antegrade conduction of the AF into the ventricles. The incidence of SCD in patients with a WPW syndrome is around 0.6% per year, and risk factors for SCD include having a short antegrade bypass tract refractory period (< 250 milliseconds), short RR intervals during preexcited AF, and the presence of multiple accessory pathways.

It is important to avoid AV nodal blocking agents in a patient who presents with a preexcited tachycardia, as this has the potential to increase the refractory period of the AV node and facilitate conduction down the accessory pathway. Administration of AV nodal blocking agents such as verapamil, diltiazem, and digoxin is contraindicated in this setting. Intravenous β-blockers are ineffective in this setting and may have adverse hemodynamic consequences.

Flecainide, a class IC antiarrhythmic agent, can be used to slow the ventricular rate in patients who have AF with rapid ventricular rates associated with preexcitation by shortening the shortest preexcited cycle length during AF.

Patients with WPW syndrome and syncope or with a short antegrade bypass tract refractory period require immediate DCC followed by catheter-based ablation of the accessory pathway as the preferred therapy. Ablation of the bypass tract does not necessarily prevent recurrence of the AF, but it should be noted that following this ablation the management of AF is similar to that of patients without preexcitation.

D. AF in pregnancy. AF occurs infrequently during pregnancy and when it does it usually has an identifiable cause, such as mitral valve disease, thyroid disease, or pulmonary processes. The ventricular rate can be controlled with digoxin, β-blockers, or a nondihydropyridine calcium channel blocker. Currently available antiarrhythmic medications cross the placenta and are excreted in breast milk and should be avoided if possible in the pregnant and lactating individuals, but amiodarone, sotalol, and flecainide have all been used successfully during pregnancy in selected instances. Quinidine has the longest safety record of any antiarrhythmic agent in pregnancy and remains the agent of choice for pharmacologic conversion of AF. In the hemodynamically unstable patient, DCC can be performed without any concerns of fetal damage.

Anticoagulation should also be given high priority during pregnancy, given the risk of thromboembolic disease during pregnancy, and only those patients with lone AF at low risk for thromboembolic complications do not require anticoagulants.

The oral anticoagulant warfarin is generally avoided during the first trimester of pregnancy because of teratogenic effects and also during the last month of pregnancy because of bleeding concerns during delivery. Administration of unfractionated heparin either by continuous intravenous infusion in a dose sufficient to increase the activated partial thromboplastin time (aPTT) to 1.5 to 2 times control or by intermittent subcutaneous injection of 10,000 to 20,000 units every 12 hours adjusted to prolong the midinterval aPTT to 1.5 times control is appropriate. Low-molecular-weight heparin may also be considered during the first trimester and last month of pregnancy, although there are limited data on clinical outcomes with its use.

E. AF and hypertrophic obstructive cardiomyopathy (HOCM). Patients with AF and HOCM have a high risk of systemic embolic events. For this reason, it is recommended to maintain oral anticoagulation therapy in the range of an INR of 2.0 to 3.0 or alternative anticoagulation with dabigatran, rivaroxaban or apixaban in patients with HOCM and AF regardless of what the CHADS2 score is. Antiarrhythmic medications can be used to prevent recurrent episodes of AF, and although there are insufficient data comparing the various antiarrhythmics, anecdotal evidence seems to support the use of disopyramide in combination with a β-blocker or a nondihydropyridine calcium channel blocker.

F. AF and pulmonary disease. AF commonly develops in patients with COPD exacerbations. General recommendations include the treatment of the underlying lung process, correction of hypoxia, and of the acid–base imbalances. Medications commonly used to treat bronchospastic airway disease such as theophylline and β-adrenergic agonists can precipitate AF and decrease the ability of medications to control the ventricular rate. Antiarrhythmic medications with β-blocking properties such as sotalol, propafenone, and adenosine can worsen bronchospasm and are contraindicated in patients with severe bronchospastic airway disease. Ventricular rate control is usually achieved with nondihydropyridine calcium channel blockers such as verapamil and diltiazem.

Venous Thromboembolism and Hypercoagulable States

I. VENOUS THROMBOEMBOLISM AND HYPERCOAGULABLE STATES

A. Venous thromboembolism (VTE). Deep vein thrombosis (DVT) and pulmonary embolism (PE) represent different manifestations of the same clinical entity referred to as venous thromboembolism (VTE). It is a common, lethal disease that affects hospitalized and nonhospitalized patients, recurs frequently, is often overlooked, and can result in long-term complications, including chronic thromboembolic pulmonary hypertension (CTPH) and the postthrombotic syndrome (PTS). Although PE is the third most common cause of hospital-related death in the United States, less than half of all hospitalized patients at risk for VTE receive adequate prophylactic treatment. Most hospitalized patients have at least one or more risk factors for VTE, and **without prophylaxis, the incidence of hospital-acquired DVT is 10% to 20% among medical patients and even higher among surgical patients (15% to 40%)**.

1. **Deep vein thrombosis.** The lower extremities are the most common sites for DVT, but other affected sites include the upper extremities and the mesenteric and pelvic veins. The main goal in the management of DVT is the prevention of PE and PTS. Proximal lower extremity DVTs (popliteal vein and above) have an estimated risk of PE of 50% if not treated. Approximately 25% of calf vein thrombi propagate (in the absence of treatment) to involve the popliteal vein or above.
2. **Pathogenesis and risk factors.** Virchow's triad still forms the best framework for understanding the pathogenesis of VTE. **The triad includes *stasis, hypercoagulability,* and *injury to the vessel wall.*** There are both inherited and acquired risk factors for hypercoagulability. The most common **inherited** risk factors include **factor V Leiden** (FVL) and **prothrombin gene mutation (G20210A)**; deficiency of the natural **anticoagulant protein C (PC), protein S (PS)**, and **antithrombin (AT)**; **hyperhomocysteinemia**; and **elevated factor VIII** levels. Acquired risk factors include **immobilization, surgery**, **trauma**, **pregnancy**, use of oral **contraceptives** (OCPs) or **hormone replacement** therapy (HRT), **malignancy**, **antiphospholipid syndrome** (lupus anticoagulant and/or anticardiolipin antibodies), **heparin-induced thrombocytopenia** (HIT), **myeloproliferative** disorders, **smoking**, **obesity** (body mass index [BMI] > 30), **inflammatory bowel disease**, **central venous catheters** or **pacemakers**, and **the nephrotic syndrome**.
3. **Clinical manifestations.** Typical symptoms of DVT in the upper and lower extremities include pain and swelling. Signs of DVT on physical examination may include increased warmth, tenderness, edema, the presence of dilated veins (collaterals), erythema, and, in extreme situations, cyanosis or gangrene. Various signs such as Homans' sign (dorsiflexion of the ankle with the knee at 30° flexion causing calf pain), Louvel's sign (worsening of pain with coughing or sneezing), and Lowenberg's sign (more pain on the affected leg after inflation of a sphygmomanometer around each calf) have been described, but these are

neither sensitive nor specific for the diagnosis. A limb-threatening manifestation of DVT, **phlegmasia cerulea dolens**, occurs most often in the setting of malignancy, HIT, or other hypercoagulable conditions in which the thrombus completely occludes venous outflow, causing massive limb swelling, hypertension in the capillary bed, and eventually ischemia and necrosis. Phlegmasia cerulea dolens is a vascular emergency requiring leg elevation, anticoagulation, and, in select cases, thrombolysis or surgical or catheter-based thrombectomy. Fasciotomy may also be required to relieve associated compartmental syndromes.

4. **Diagnosis**
   a. **Clinical examination** is unreliable in the diagnosis of DVT, as symptoms and signs are often insensitive and nonspecific. Pretest probability scores improve the utility of further testing. For example, using the Wells score (Table 25.1), patients in the low pretest probability category have a 96% negative predictive value for DVT (99% if the D-dimer is negative as well), but the positive predictive value in patients with a high pretest probability is < 75%, supporting the need for further diagnostic testing to identify patients with thrombosis.

TABLE 25.1 Pretest Probability of Deep Vein Thrombosis (Wells Score)

Clinical feature[a]	Score
Active cancer (treatment ongoing or within previous 6 mo of palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for more than 3 d or major surgery, within 4 wk	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling by more than 3 cm when compared with the asymptomatic leg (measured 10 cm below tibial tuberosity)	1
Pitting edema (greater in the symptomatic leg)	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis as likely or greater than that of DVT	–2
Score	
High	3 or greater
Moderate	1 or 2
Low	0 or less
Modified score (adds one point if there is a previously documented DVT)	
Likely	2 or more
Unlikely	1 or less

DVT, deep vein thrombosis.
[a]In patients with symptoms in both legs, the more symptomatic leg is used.

b. Venography has been the gold standard test for the diagnosis of DVT in the past. The presence of an intraluminal filling defect is diagnostic, although abrupt cutoffs, nonfilling of the deep venous system, and/or demonstration of collateral flow may also serve as evidence for the presence of DVT. However, because venography is invasive and requires the use of potentially harmful contrast agents, it has largely been replaced by noninvasive tests such as duplex ultrasonography.

c. Duplex ultrasonography has a sensitivity and specificity of about 95% and 98%, respectively, for the detection of proximal DVT in symptomatic patients; however, it is operator dependent and is less sensitive in asymptomatic individuals and for thrombi located in the calf veins. **An inability to compress the vein with the ultrasound transducer is diagnostic for DVT**. Other findings suggestive, but not diagnostic, of an acute DVT include venous distention or absent or decreased spontaneous flow. Diagnosis of recurrent DVT is more challenging, given the high incidence of persistently noncompressible veins after an initial event. Other limitations of compression ultrasonography include difficulty in detecting isolated thrombi in the iliac veins or femoral veins within the abductor canal. False positives may occur when pelvic masses result in isolated noncompressibility of the common femoral veins.

d. D-Dimer. The sensitivity and negative predictive value of this test are high. The combination of a **low pretest probability and a negative D-dimer has an extremely high negative predictive value for VTE (approximately 99%)**. A positive D-dimer, however, is nonspecific, and other diagnostic testing should be performed.

e. Other diagnostic tests less frequently used to detect DVT include magnetic resonance venous imaging and computed tomography (CT). These tests are mainly helpful in the diagnosis of DVT in the pelvic veins, inferior vena cava (IVC), or mesenteric veins.

5. Treatment

a. The main goals of treatment for DVT include relief of symptoms and prevention of PE, CTPH, PTS, and recurrent VTE. Once the diagnosis of DVT is confirmed, **anticoagulation should be started immediately unless there is a contraindication**. Initial therapy should include heparin, low-molecular-weight heparin (LMWH), or fondaparinux followed by an oral anticoagulant (vitamin K antagonist or VKA). LMWH and fondaparinux are renally cleared, and although the LMWHs can be given in patients with renal insufficiency after dose adjustment, both are contraindicated in patients requiring dialysis.

Weight-based dosing of unfractionated heparin (UFH) (80 U/kg bolus followed by 18 U/kg/h intravenous [IV] infusion) has been shown to achieve a therapeutic activated partial thromboplastin time (aPTT) more rapidly than fixed-dose regimens. The target aPTT has traditionally been 1.5 to 2.5 times the control aPTT; however, the actual therapeutic aPTT range varies among laboratories because of their use of different aPTT reagents. The American College of Chest Physicians (ACCP) and the College of American Pathologists now advocate the use of an anti-factor Xa assay to establish a heparin dose–response curve for the aPTT ratio (of each laboratory), using concentrations that correlate to therapeutic heparin levels of 0.3 to 0.7 IU/mL determined by factor Xa inhibition. The aPTT should not be followed in patients with an abnormal baseline aPTT (e.g., in patients with lupus anticoagulant) and in patients who require unusually high doses of heparin such as in AT deficiency. In these situations, the anti-factor Xa assay should be used. UFH can also be administered subcutaneously as an alternative to IV administration, and several dosing nomograms have been recommended. One approach is to give an initial IV bolus of 5,000 U followed by a subcutaneous dose of 17,500 U twice daily on the first day. Blood for an aPTT is drawn 6 hours after

the initiation dose, and subsequent doses are adjusted accordingly to achieve an aPTT 1.5 to 2.5 times the control. Another fixed-dose nomogram recommends a subcutaneous loading dose of 333 U/kg followed by fixed doses of 250 U/kg subcutaneously every 12 hours without the need for aPTT monitoring.

LMWH is administered as a weight-based subcutaneous injection. Enoxaparin, the most commonly used agent in the United States, is given either as a once-daily injection (1.5 mg/kg/d) or twice per day (1 mg/kg every 12 hours). No monitoring is required except in obese, pediatric, or pregnant patients or patients with renal insufficiency. The anti-Xa level using LMWH as a reference standard should be measured 4 hours after an injection. The therapeutic range is 0.5 to 1.0 IU/mL for the 12-hour regimen and ≥ 1.0 IU/mL for the daily dose.

Once anticoagulation with UFH or LMWH is begun, a VKA may be initiated. The overlap should be continued for a minimum of 4 to 5 days and until the international normalized ratio (INR) is within the target range of 2.0 to 3.0 for two consecutive days to permit adequate depletion of vitamin K–dependent coagulation factors.

Fondaparinux, an indirect factor Xa inhibitor, is approved by the US Food and Drug Administration (FDA) for use as DVT prophylaxis in patients undergoing orthopedic procedures (total hip and knee arthroplasty) and abdominal surgery. It is also approved as treatment for acute DVT and PE when used in combination with a VKA. Its efficacy and safety in comparison with LMWH for the treatment of acute DVT and in comparison with IV UFH for the treatment of PE have been shown in large randomized controlled trials. Fondaparinux is administered as a once-daily subcutaneous injection of 2.5 mg for DVT prophylaxis and 5, 7.5, or 10 mg based on body weight (< 50, 50 to 100, and > 100 kg, respectively) for the treatment of DVT or PE. Fondaparinux is contraindicated in patients with severe renal impairment (creatinine clearance < 30 mL/min) and bacterial endocarditis. When used as DVT prophylaxis, fondaparinux is also contraindicated in patients with body weight < 50 kg who are undergoing hip fracture, hip replacement or knee replacement surgery, and abdominal surgery.

Thrombolytic therapy for DVT may be beneficial in select individuals and is preferably administered locally via a catheter-directed approach. Systemic lysis is also an option if a catheter-directed approach is not available. Both routes carry an increased risk of systemic hemorrhage compared with standard anticoagulation alone. Although it has been suggested that the use of thrombolytics promotes early recanalization and minimizes the incidence of PTS, their role in DVT treatment in the absence of a threatened limb is still unclear. The current ACCP guidelines recommend against their routine use in patients with DVT, except for those patients (without contraindication) with an extensive acute proximal DVT (ileofemoral DVT) or individuals at risk for limb gangrene secondary to venous occlusion.

Damage to the venous valves from lower extremity DVT and venous hypertension can lead to the development of PTS, a condition characterized by leg edema, skin changes such as hyperpigmentation and lipodermatosclerosis, pain, and, in severe cases, stasis ulceration. The incidence of this complication is drastically reduced with the use of **compression stockings**, and current guidelines recommend the use of stockings at a pressure of 30 to 40 mm Hg at the ankle for 2 years after an episode of DVT. In addition, early ambulation as tolerated after diagnosis is encouraged, as mobile patients with DVT do not require bed rest.

b. Vena caval interruption. Current guidelines recommend against the routine insertion of IVC filters for the treatment of DVT. **Indications for placement of IVC filters are as follows: a contraindication to anticoagulation,**

a complication from anticoagulation, or recurrent thromboembolization despite adequate anticoagulant therapy. Relative indications for IVC filters are massive PE, iliocaval DVT, free floating proximal DVT, cardiac or pulmonary insufficiency, high risk of complications from anticoagulation (frequent falls and ataxia), or poor compliance. **Retrievable** filters can be considered for situations in which anticoagulation is temporarily contraindicated or there is a short duration of PE risk. **IVC filter alone is not an effective therapy** for DVT, and resumption of anticoagulation as soon as risk of bleed is acceptable is recommended.

c. **Duration of treatment.** The **duration** of treatment following the diagnosis of DVT is **dependent on the risk of recurrence**. Risk factors for recurrence include an idiopathic DVT, underlying hypercoagulable states (listed in subsequent text), and malignancy. In addition, placement of a permanent IVC filter, elevated D-dimer levels, advanced age, male sex, and increased BMI also place individuals at a higher risk for recurrence. The risk of recurrence is low while patients are on anticoagulation; however, clinicians must weigh the risk of bleeding against the risk of new thrombosis.

Current guidelines **recommend 3 months of anticoagulation** with a VKA targeting **an INR of 2 to 3** for patients with a **first episode of DVT secondary to a transient cause**. Anticoagulation with a VKA for at least **6 to 12 months** with a target **INR of 2 to 3** is recommended for patients with a **first episode of idiopathic DVT**, although consideration should also be given for indefinite anticoagulation in this situation. Patients with the antiphospholipid syndrome, homozygous for FVL, or doubly heterozygous for FVL and prothrombin gene mutation should be considered for **indefinite anticoagulation**. Long-term (indefinite) anticoagulation is also recommended in patients with malignancy for as long as the cancer remains active, and in patients who have unexplained recurrent DVTs.

6. **Calf vein thrombosis.** Anticoagulation is generally indicated for symptomatic calf vein DVT or when there is propagation into the **popliteal vein or more proximally**. Current guidelines recommend 3 months of treatment with a VKA targeting an INR of 2 to 3 for patients with a first episode of symptomatic DVT confined to the calf veins secondary to a transient cause. Monitoring calf vein thrombosis for propagation into the proximal veins with serial ultrasonography (once or twice weekly for 2 to 3 weeks) without anticoagulation represents an alternative approach to treatment for individuals with high risk of bleeding.
7. **Superficial venous thrombosis** frequently occurs as a complication of an IV line in an upper extremity, but may occur spontaneously in the upper or lower extremities. Anticoagulation is generally not required due to the lower risk of PE, unless the thrombosis propagates into the deep venous system or if the event is spontaneous. Guidelines recommend intermediate doses of heparin or LMWH for at least 4 weeks for spontaneous superficial thrombophlebitis. Alternatively, a VKA can be used for 4 weeks. A recent study showed that daily fondaparinux at a dose of 2.5 mg for 45 days was effective in the treatment of lower extremity symptomatic superficial thrombophlebitis without serious side effects.
8. **Upper extremity DVT.** Upper extremity DVT is most often related to central venous catheter placement and/or pacemaker devices. Other less common causes include thoracic outlet syndrome, Paget-von Schröetter syndrome (also referred to as effort thrombosis), and hypercoagulable conditions including malignancy. Patients may be asymptomatic but more frequently complain of arm swelling and pain. Anticoagulation is indicated if there are no contraindications. Thrombolysis should be considered in younger patients with effort thrombosis, who have a low risk of bleeding and symptoms of acute onset. Determination of the length of anticoagulation with a VKA should be decided using the same processes described for acute lower extremity DVTs.

B. PE. It is difficult to approximate the true incidence of PE, but there are estimates that as many as 300,000 Americans have a fatal PE each year and as many as 34% of affected individuals present with sudden death. **The majority of patients die because of a failure in diagnosis rather than inadequate therapy**. In fact, the mortality rate for PE without treatment is approximately 30%, whereas it is only 2% to 8% with adequate treatment. PE remains the most common preventable cause of hospital death in the United States.

1. **Pathophysiology and symptoms.** Hemodynamic collapse related to PE results from a combination of vascular obstruction from thrombus and vasoconstriction caused by inflammatory mediators and hypoxia. Elevated pulmonary vascular resistance results in decreased right ventricular outflow, leading to a decrease in preload and cardiac output resulting in hypotension. To overcome an obstruction of 75% and maintain pulmonary perfusion, the right ventricle must generate a systolic pressure in excess of 50 mm Hg and a mean pulmonary artery pressure > 40 mm Hg. The normal right ventricle is unable to generate these pressures, and right heart failure and cardiac collapse ensue. In addition, elevated right ventricular wall tension can lead to decreased right coronary artery flow and ischemia. Cardiopulmonary collapse from PE is more common in patients with coexisting coronary artery disease (CAD) or underlying cardiopulmonary disease.

   PE may present as one of the following three syndromes: (a) **acute cor pulmonale**, (b) **pulmonary infarction**, or (c) **dyspnea**. Patients presenting with acute cor pulmonale, as manifested by the sudden development of dyspnea, cyanosis, shock, or syncope, usually have a massive PE leading to cardiovascular collapse. Patients with pulmonary infarction usually present with pleuritic chest pain, dyspnea, and hemoptysis, and an audible friction rub may be heard. The majority of patients present with generalized symptoms of chest pain, dyspnea, and malaise.

2. **Diagnosis**
   a. Several pretest probability scores have also been developed for the diagnosis of PE similar to those for the diagnosis of DVT. In a validation study of the Wells clinical decision rule, only 0.5% of patients who were unlikely to have PE and had a negative D-dimer had subsequent nonfatal VTE.
   b. **Troponin.** Cardiac troponins have been evaluated in the setting of acute PE, and elevated levels correlate with electrocardiographic and echocardiographic findings of right ventricular pressure overload. Elevations in this marker can be seen in patients with and without CAD, but the overall mortality and inhospital complications are higher in patients with acute PE and elevated cardiac troponin than in patients without elevated cardiac troponin.
   c. **Brain natriuretic peptide** elevation in the absence of renal dysfunction is also a marker of right ventricular dysfunction in patients with PE. Like elevated troponin levels, these elevated levels have also been shown to be predictors of adverse outcome in patients with acute PE.
   d. **Arterial blood gas.** PE can result in significant hypoxia, but in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, 26% of patients with angiographically proven PE had Pa_{O_2} > 80 mm Hg. Similarly, a **normal alveolar–arterial gradient does not preclude the diagnosis of PE**. Therefore, a normal Pa_{O_2} cannot rule out PE; however, hypoxia in the absence of cardiopulmonary disease should raise the suspicion for this diagnosis. In patients with cardiopulmonary collapse, a normal Pa_{O_2} suggests that PE is an unlikely cause.
   e. **Chest radiography** may be more helpful in establishing other diagnoses. When present, findings are nonspecific and include pleural effusion, atelectasis, and consolidation. The classic signs, including the Westermark sign (regional oligemia), Hampton's hump (pleural-based, wedge-shaped shadow), and Palla's sign (enlarged right inferior pulmonary artery), are uncommon.

f. **Electrocardiography.** Like chest radiography, the major utility of the electrocardiogram (ECG) in the diagnosis of PE is to rule out other major diagnoses, such as acute myocardial infarction (MI). The most specific finding on an ECG is the classic $S_1Q_3T_3$ pattern, but the most common findings are nonspecific ST-segment and T-wave changes. Other commonly reported findings include sinus tachycardia, atrial fibrillation, and right bundle branch block.

g. **Echocardiography.** More than 50% of hemodynamically stable patients with PE will not have evidence of right ventricular dysfunction on transthoracic echocardiography (TTE). Patients with **hemodynamic collapse, however, will generally have severe right ventricle dysfunction**, and TTE can provide rapid bedside assessment in these critically ill patients. TTE findings include right ventricular dilation, right ventricular hypokinesis, tricuspid regurgitation, septal flattening, paradoxical septal motion, diastolic left ventricular impairment secondary to septal displacement, pulmonary artery hypertension, lack of inspiratory collapse of the IVC, and, rarely, direct visualization of the thrombus. In patients with large PE, it has been observed that despite moderate or severe right ventricular free wall hypokinesis there is relative sparing of the apex. This finding is referred to as **McConnell's sign** and has a specificity of 94% and a positive predictive value of 71% for PE. McConnell's sign may be useful in discriminating right ventricular dysfunction due to PE versus other causes.

h. **Ventilation–perfusion (V/Q) scanning. V/Q** scanning is now considered a second-line imaging method for the diagnosis of PE. **V/Q** scans are helpful in patients who have normal chest radiography or who are unable to have CT scanning, such as those with renal insufficiency, contrast allergy, or pregnancy. The results of PIOPED suggest that **V/Q** scanning is helpful if the scan is normal or at high probability for PE (87% of patients with high-probability scans had PE, but only 4% of patients with normal scans had PE). Intermediate-probability or low-probability scans are the most common finding, however, occurring in approximately 70% of patients in the PIOPED study. In addition, patients who had a high or intermediate clinical suspicion for PE but a low-probability scan still had a 40% and 16% rate, respectively, of PE diagnosed by pulmonary angiography. Hence, it is currently advised that **patients with a high or intermediate clinical suspicion for PE but a low-probability V/Q scan have additional tests to confirm or refute the diagnosis**.

i. **Computed tomography pulmonary angiography (CTPA).** Because of its wide availability and the ability to directly visualize thrombus, **CT imaging has become the standard imaging technique for the diagnosis of acute PE**. CTPA not only allows direct visualization of the thrombus but also has great value in excluding other diseases, including aortic dissection, pneumonia, or malignancy. It is especially useful in evaluating central PE (thrombus is seen as an intraluminal filling defect), and although the diagnostic yield for peripheral or subsegmental PE was low initially, the use of multidetector CTPA has greatly increased its sensitivity and specificity for the diagnosis of small peripheral or subsegmental PEs. CT venography of the abdomen and pelvis can also allow direct evaluation of the IVC and pelvic veins. This may be of value in selected cases as recent studies have shown that the routine use of CT venography of the pelvis during CTPA does not significantly improve the detection of VTE and therefore should not be performed routinely in all patients being evaluated for PE. The major disadvantages of CT are radiation exposure, higher cost, and the possibility of contrast-induced nephrotoxicity. A meta-analysis of 23 studies including 4,657 patients who were suspected of having PE but had normal CT scans found that only 1.4% developed VTE and 0.51% developed fatal PE by 3 months. These rates are similar to those in other studies involving patients who had suspected PE but were found to have normal pulmonary angiograms.

j. **Pulmonary angiography** remains the gold standard diagnostic test for PE, but it is used infrequently due to the advent of CT scanning. Four injections with four views (right and left anteroposterior and right and left oblique) are performed. In some situations where a lung scan shows perfusion abnormalities and is nondiagnostic for PE, selective angiography of the abnormal area may be considered so as to limit the amount of contrast needed. In experienced centers, associated morbidity and mortality are low.

k. **Magnetic resonance angiography** (MRA) may be an alternative to CT for the diagnosis of PE in patients who have contrast allergy or for whom avoidance of radiation exposure is desired. In PIOPED III, MRA had insufficient sensitivity and a high rate of technically inadequate images. Addition of magnetic resonance venography (MRV) to MRA improves sensitivity; however, 52% of patients in the study had a technically inadequate study. At the current time, an MRA/MRV should be considered only at those centers with experience with this modality and only for patients for whom standard tests are contraindicated.

3. **Treatment.** Anticoagulation with heparin, LMWH, and fondaparinux followed by the addition of a VKA and supportive care has remained the standard of care in the management of acute PE. **Current guidelines recommend initial treatment with anticoagulants for patients with a high clinical suspicion for PE while awaiting the results of diagnostic testing.** For patients with nonmassive PE, subcutaneous LMWH, IV UFH, or fondaparinux are recommended as initial treatment. In patients with acute nonmassive PE, LMWH is recommended over UFH. A VKA may be initiated together with IV UFH, LMWH, or fondaparinux and should be continued for a minimum of 4 to 5 days and until the INR is stable and ≥ 2.0.

   a. **Thrombolysis** for the treatment of acute PE is highly individualized, as there have been no clearly established short-term mortality effects. Because of favorable outcomes with prompt recognition and anticoagulation for PE, **thrombolysis should be reserved for hemodynamically unstable patients with acute massive PE and a low risk of bleeding**. It is unclear whether there is any benefit for thrombolytic therapy in patients who are hemodynamically stable but who have echocardiographic evidence of right ventricle dysfunction. Streptokinase, urokinase (no longer available in the United States), and tissue plasminogen activator are the current agents approved by the FDA. Current guidelines recommend the use of systemic thrombolytic therapy in patients who are hemodynamically unstable. Local administration of thombolytic therapy via a catheter is not suggested, owing to the risk of hemorrhage at the insertion site.

   b. Pulmonary embolectomy was the first definitive therapy to be performed for PE. There have been no randomized trials evaluating embolectomy, and the primary use of this procedure is in patients with shock and a contraindication to thrombolysis. Other investigational therapies include catheter-based embolectomy procedures that utilize aspiration, fragmentation, or rheolytic therapy. As of yet, there are currently no guidelines for the use of these therapies.

4. **New oral anticoagulants.** Until recently, warfarin was the only available oral anticoagulant for the treatment of VTE. Multiple new oral agents, with different mechanisms of action, have been evaluated in phase III clinical trials and have become available in markets outside the United States. These medications have the potential to revolutionize management of VTE. The agents that are most advanced in their development are the oral direct thrombin inhibitor (DTI), dabigatran etexilate, and oral direct factor Xa inhibitors (such as apixaban and rivaroxaban).

   These new oral anticoagulants in general have a more rapid onset of action, which may obviate the need for parenteral anticoagulation in the initial treatment

of VTE. Additionally, because these agents have stable pharmacodynamics (unlike warfarin), routine monitoring is not required. This makes them more favorable for use as long-term anticoagulants. A major disadvantage of these medications, however, is the current lack of an antidote in case of bleeding complications.

a. Oral direct thrombin inhibitors. Ximelagatran was the first oral DTI to complete phase III clinical trials; however, because of the high incidence of hepatotoxicity, it was withdrawn from the market.

Dabigatran etexilate—a prodrug—has been shown in a randomized, double-blind, noninferiority trial (RE-COVER) to be as effective as warfarin for the treatment of acute VTE with a similar safety profile. Dabigatran was given in a fixed dose without the need for laboratory monitoring. Dabigatran was also not inferior to subcutaneous enoxaparin in the prevention of VTE after total knee or total hip arthroplasty with similar bleeding risks. Dabigatran is not approved yet by the FDA for the prevention and treatment of VTE; however, it has been approved recently for the prevention of stroke and systemic embolism in patients with nonvalvular atrial fibrillation based on the data from the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) trial. It requires dose adjustments for patients with a creatinine clearance of 15 to 30 mL/min and is not recommended if the creatinine clearance is ≤ 15 mL/min.

b. Oral direct factor Xa inhibitors. Rivaroxaban is an oral direct factor Xa inhibitor with a relatively short half-life of 5 to 9 hours and rapid onset of action of 2.5 to 4 hours.

Oral rivaroxaban given alone was not inferior to subcutaneous enoxaparin followed by warfarin for the treatment of acute symptomatic DVT, with a similar safety profile (EINSTEIN-DVT trial).

Rivaroxaban has also been shown to be superior to enoxaparin for the prevention of VTE following knee and hip replacement surgery, with a similar safety profile in the RECORD trials. It was recently approved by the FDA for the prevention of VTE in adults following hip and knee arthroplasty.

Rivaroxaban was also approved recently for the prevention of stroke and systemic embolization in patients with nonvalvular atrial fibrillation based on the results of ROCKET-AF trial. It should not be used in patients with severe renal insufficiency or significant hepatic impairment.

Apixaban is another oral direct factor Xa inhibitor with promising data. Apixaban was found to be comparable to warfarin in a small phase II trial for the treatment of DVT. Apixaban was superior to enoxaparin when given using the European regimen (40 mg daily starting on the evening before surgery) in preventing VTE after knee and hip replacement. However, in another study, apixaban failed to meet the noninferiority standards for the prevention of VTE after knee replacement when compared with enoxaparin (given in the North American regimen of 30 mg every 12 hours starting 12 to 24 hours after surgery). Abixaban has been approved in Europe for the prevention of VTE in adults following hip and knee arthroplasty but is not yet approved in the United States. Similar to dabigatran and rivaroxaban, abixaban will likely also to be approved soon in the United States for the prevention of stroke in nonvalvular atrial fibrillation based on the data from ARISTOTLE trial.

C. VTE prophylaxis. Thromboprophylaxis should be provided to all hospitalized patients. Unfortunately, studies show that less than half of hospitalized patients receive appropriate VTE prophylaxis. Individuals who are considered at greatest risk are those over 40 years and patients who are immobilized or who have an underlying medical conditions (MI, stroke, congestive heart failure, and pneumonia), suffered trauma, or have undergone recent surgical procedures (especially hip fracture, total knee or hip replacement, or neurosurgical procedures). There are two major forms of prophylaxis, **mechanical and pharmacologic**. Those who cannot receive prophylactic anticoagulation should be prescribed mechanical modalities such as intermittent pneumatic

compression devices. Pharmacologic prophylaxis can be achieved by a number of agents, including UFH, LMWH, fondaparinux, a VKA, and rivaroxaban, which has been approved recently for VTE prophylaxis after hip and knee replacement surgery. Other new oral anticoagulant agents (dabigatran and apixaban) are available outside the United States for prophylaxis and will likely be available sometime in the near future in the United States. In high-risk populations such as those with hip or knee replacement, a combination of mechanical and pharmacologic therapies should be considered. In select surgical procedures, extended prophylaxis is recommended. For example, extended prophylaxis for up to 28 to 35 days is recommended for patients who have had a hip fracture or who undergo total hip replacement surgery.

II. HYPERCOAGULABLE CONDITIONS. Conditions that predispose persons to an increased risk of thrombosis are referred to as hypercoagulable states or thrombophilia. These conditions are being identified more frequently and may be classified as inherited or acquired. Hypercoagulability testing should be considered in individuals with idiopathic VTE, family history of clotting, a first thrombotic event before the age of 50 years, thrombosis at unusual locations, resistance to anticoagulation, and those with recurrent thromboses.

A. FVL and prothrombin gene mutation. Activated PC inactivates factors Va and VIIIa and is one of the mechanisms by which the balance between clotting and bleeding is maintained. The autosomal dominant acquisition of a single-point mutation (FVL) in the factor V gene renders the protein factor V resistant to inactivation by activated PC. Both homozygous and heterozygous states are at an increased risk of venous thrombosis, with a 50-fold to 100-fold increase in the homozygous state and a 3-fold to 7-fold increase in the heterozygous state. The FVL mutation is more prevalent in persons of European and Scandinavian ancestry.

The prothrombin gene mutation G20210A (PT G20210A) is also inherited as an autosomal dominant mutation and may lead to a higher plasma level of prothrombin. It is also more common in those of Caucasian ancestry and confers a 2.8-fold increased risk of VTE. The role of FVL and PT G20210A mutations in arterial thrombosis is unclear. There is only a modest association between inherited thrombophilias and major arterial thromboses such as MI, stroke, or peripheral arterial disease. Therefore, routine screening for these mutations is not warranted in most patients with arterial thrombosis. In young persons who develop arterial events, however, abnormalities in hemostasis may play a role, particularly in the presence of other risk factors such as smoking and OCP use, and additional testing may be warranted. FVL and PT G20210A are associated with VTE during pregnancy, OCP use, and HRT. For example, the annual risk of DVT is 3 per 10,000 in women without FVL who use OCPs, 5.7 per 10,000 in women with FVL who do not use OCPs, and 28.5 per 10,000 in women with FVL who use OCPs. FVL can be identified by evaluating for activated PC resistance in plasma or by gene analysis using polymerase chain reaction. The prothrombin gene mutation is also identified by genetic analysis. There are no clear evidence-based guidelines for managing patients with thrombosis in the setting of these thrombophilias. In general, acute thrombosis should be managed in a standard fashion, but the duration of therapy is less clear, and the benefits of long-term anticoagulation must be weighed against the risks of bleeding. Current guidelines recommend **long-term therapy for patients who are homozygous for FVL or who are doubly heterozygous for FVL and PT G20210A,** as well as individuals with the **antiphospholipid syndrome**. Asymptomatic gene carriers should receive prophylaxis in high-risk situations.

B. Defects in the natural anticoagulants (PC, PS, and AT). Deficiency of any of the three natural anticoagulants is associated with an increased risk of venous thrombosis. All are inherited as autosomal dominant defects and are further subclassified based on reduction in their levels or defective quality of the protein. PS acts as a cofactor in the inactivation of factors Va and VIIIa by activated PC. It is bound to C4-binding protein (an acute phase reactant) in the plasma. Levels of PS and PC are lower in conditions such as disseminated intravascular coagulation (DIC), inflammatory states,

nephrotic syndrome, acute thrombosis, and liver disease. Pregnancy and OCP use can also decrease the levels of PS. Both PC and PS levels are lowered by warfarin therapy, and, therefore, these tests should not be assayed in patients who are receiving VKAs. Similarly, initiation of warfarin therapy without concomitant anticoagulation in the setting of acute VTE may lead to warfarin-induced skin necrosis (manifested as painful necrosis of the skin, primarily in fatty areas including the breast, buttocks, and thighs). Treatment includes stopping warfarin, administering vitamin K and fresh frozen plasma to replete levels, and using an alternative anticoagulant. AT is produced by the liver and endothelial cells and functions by inactivating thrombin and factors Xa, IXa, XIa, and XIIa. Homozygous states are incompatible with life. Levels are also low in the following: those with DIC, sepsis, liver disease, nephrotic syndrome; with the use of OCPs; and during pregnancy. As previously discussed, patients with AT deficiency may have resistance to heparin because it exerts its anticoagulant effect through AT. AT concentrates are available and can be used temporarily to correct this deficiency.

C. Homocysteine. Hyperhomocysteinemia is a risk factor for venous and arterial thromboses. It may be inherited, and genetic defects causing a deficiency of cystathionine β-synthase or a mutation in methylenetetrahydrofolate reductase have been reported. Acquired causes include deficiencies in vitamin B_{12}, B_6, or folate; smoking; and liver or renal failure. Treatment with folate in doses between 0.5 and 5 mg is usually effective in reducing the levels of homocysteine; however, this does not reduce the risk of major cardiovascular events, symptomatic venous thrombosis, or recurrent venous thrombosis.

D. Heparin-induced thrombocytopenia. HIT is a common, underrecognized but potentially devastating condition in patients who receive heparin or LMWH. The reported incidence is between 3% and 5% in patients exposed to UFH and lower (< 1%) in patients exposed to LMWH. The pathogenesis of HIT involves the formation of antibodies (usually immunoglobulin G [IgG]) against a heparin–platelet factor 4 (PF4) complex. The HIT antibodies then trigger procoagulant effects through platelet and endothelial cell activation, as well as thrombin generation leading to both microvascular and macrovascular thromboses. The clinical spectrum of HIT ranges from isolated thrombocytopenia without thrombosis (referred to as isolated HIT) to HIT(T), which is associated with both arterial and venous thromboses. Other manifestations of HIT may include hypotension from adrenal hemorrhage secondary to adrenal vein thrombosis and ensuing infarction, skin necrosis at injection sites, or venous limb gangrene. HIT should be suspected in any patient who develops thrombocytopenia while receiving heparin or LMWH; any patient who develops a < 50% decline in platelet count after the initiation of either anticoagulant; or any patient who develops new thrombosis or extension of an existing thrombosis while receiving either of these agents. In patients with HIT and de novo exposure to heparin, thrombocytopenia (platelet count < 150,000 per μL) usually occurs between days 5 and 14 (with day of heparin exposure being day 0). In patients with a recent exposure to either agent (generally within the last 100 days), HIT may develop sooner and is referred to as rapid-onset HIT. This complication may also develop 9 to 40 days after heparin or LMWH has been discontinued and is known as delayed-onset HIT. Laboratory tests to aid in the diagnosis of HIT include functional assays (detection of heparin-dependent platelet activation in the presence of UFH or LMWH), such as heparin-induced platelet aggregation and serotonin release assays (SRA), and antigen assays (immunoassays), which detect IgG, IgM, or IgA antibodies that bind UFH to PF4. The SRA has the highest sensitivity and specificity for the diagnosis of HIT. The first step in the treatment of HIT is the prompt discontinuation of all sources of heparin or LMWH, including heparin flushes, heparin-coated catheters, any intermittent use of heparin during dialysis, and total parenteral nutrition or angiography. However, approximately 20% to 53% of patients with HIT will develop thrombosis (many within the first month) when treated only with discontinuation of heparin or LWMH alone. Therefore, the

initiation of an alternative anticoagulant, unless contraindicated, is recommended. **DTIs**, including lepirudin and argatroban (both approved by the FDA), may be used initially. Lepirudin has a longer half-life and is metabolized primarily by the kidney. The aPTT can be used to monitor therapy with a target range of 1.5 to 2.5 times the baseline level measured 4 to 6 hours after dose adjustments. Argatroban has a shorter half-life than lepirudin and is primary metabolized in the liver. The goal for aPTT is 1.5 to 3.0 times the baseline level. There are no agents available that reverse the effects of either drug; therefore, if bleeding develops, prompt discontinuation should be considered. Once platelet counts are more than 100,000 to 150,000 mm^3, warfarin may be started at a low dose (2.5 to 5 mg preferred). Early introduction or higher doses of warfarin may lead to venous limb gangrene or warfarin-induced skin necrosis. Overlapping the DTI with the VKA should be continued for at least 5 days and not discontinued until the INR is therapeutic for two consecutive days. Argatroban falsely elevates the INR; therefore, it should not be discontinued until INR > 4, as recommended by the manufacturer. After cessation of argatroban, the INR should be rechecked within a few hours to confirm that it is between 2 and 3. The duration of anticoagulation for patients with HIT is generally determined by the location and type of thrombosis. In patients without thrombosis (isolated HIT), the duration of anticoagulation is less clear, but given the high incidence of thrombosis within the first month, it is reasonable to continue anticoagulation for at least a month in the absence of contraindications.

E. Antiphospholipid antibodies are a heterogeneous group of autoantibodies that, if present in a patient with thrombosis, lead to the antiphospholipid syndrome. Antiphospholipid antibodies can be divided into three groups: (a) anticardiolipin antibodies, (b) lupus anticoagulants, and (c) β_2 glycoproteins. They are often associated with other autoimmune conditions and can cause recurrent pregnancy loss, as well as arterial or venous thrombosis. Thrombocytopenia is also an occasional feature of this syndrome. Anticardiolipin antibodies are detected and quantified using an enzyme-linked immunosorbent assay and may be IgG, IgM, or IgA. IgG titers have been correlated more often with thrombosis. Lupus anticoagulants prolong phospholipid-dependent blood clotting times, and it has been reported that there is about a fivefold increased risk of thrombosis in patients with this finding. Once a thrombotic event occurs, long-term therapy with warfarin must be considered. A higher target INR had been considered necessary in the past (approximately ≥ 3.0), but is no longer considered necessary as data have suggested that most patients can be maintained with a target INR of 2.0 to 3.0. In those individuals that are suspected of failing adequate therapy, one strategy is to correlate the INR to factor II and factor X levels (of ≤ 20% to 30%) to ensure adequate anticoagulation. Patients with recurrent miscarriages should receive aspirin and LMWH during pregnancy.

F. Malignancy. Many malignancies induce a hypercoagulable state, and in patients with idiopathic VTE, a search for age- and gender-specific malignancies may be necessary. LMWH as monotherapy for the first 3 months before bridging to Coumadin has been shown to decrease the risk of venous thrombosis recurrence or anticoagulation failure.

G. Other conditions. Elevated factor VIII levels and the dysfibrinogenemias have also been associated with thrombosis; however, the role of deficiencies of plasminogen, tissue plasminogen activator (of the fibrinolytic system), and factor XIII polymorphisms as emerging risk factors for hypercoagulability is less clear.

CHAPTER 26

Matthew C. Bunte
Maran Thamilarasan

Aortic Aneurysm and Aortic Dissection

I. INTRODUCTION

A. Aorta. The aorta is the **principal conductance vessel** in the body and is divided into the ascending, arch, descending thoracic, and abdominal components.

1. The **ascending aorta** includes the aortic root, which contains the sinuses of Valsalva. The left and right coronary arteries arise from the left and right coronary sinuses, respectively.
2. The **aortic arch** gives rise to the great vessels of the head and arms. These include the brachiocephalic (innominate), the left common carotid, and the left subclavian arteries.
3. The **descending thoracic aorta** provides the intercostal vessels as it courses through the posterior mediastinum. The vascular supply to the anterior spinal artery is included among these vessels.
4. The **abdominal aorta** begins just after the aorta crosses the diaphragm. It provides the splanchnic and renal arteries before bifurcating to become the common iliac arteries.

B. Histology. The aorta comprises **three layers**: the intima, the media, and the adventitia.

1. The **intima** is the internal lining layer of the aorta and is easily damaged.
2. The **media** is the main structural layer of the aorta. It consists primarily of laminar layers of elastic tissue and smooth muscle in varying amounts. This structure allows for the high tensile strength and elasticity required to withstand the pressure changes of each heartbeat throughout the life of the individual.
3. The **adventitia** is the thin outer layer that anchors the aorta within the body, in addition to providing nourishment to the outer half of the wall through the vasa vasorum.

C. Physiology

1. The **elasticity of the aortic wall allows it to distend** under the pressure created during ventricular systole. In this way, the kinetic energy that was developed during ventricular systole is stored as potential energy in the distended aortic wall. Then, during ventricular diastole, the potential energy is converted back to kinetic energy by elastic recoil of the wall. Therefore, forward blood flow is maintained throughout the cardiac cycle.
2. The aorta aids in the control of **systemic vascular resistance (SVR)**. Pressure receptors in the ascending aorta and aortic arch signal the vasomotor centers of the brain via the vagus nerve. When blood pressure is elevated, the reflex response is to lower heart rate and decrease SVR. The converse is true when blood pressure is decreased.

D. Acute aortic syndromes including aortic dissection, aortic intramural hematoma (IMH), and penetrating atherosclerotic ulcer (PAU) are life-threatening disorders that require prompt diagnosis and treatment.

E. The 2010 ACC/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM Guidelines for the Diagnosis and Management of Patients with Thoracic Aortic Disease is the principal source of information discussed in this chapter. Where appropriate and unless otherwise indicated, class I guideline recommendations from this document are embedded in italics within this chapter. The level of evidence following the corresponding recommendation is provided in parenthesis.

II. AORTIC DISSECTION

A. The International Registry of Acute Aortic Dissections (IRAD). Since 1996, the IRAD has built a consortium of 24 referral centers in 12 countries dedicated to the study of acute aortic dissection that now includes over 1,600 patients. This research collaborative has provided considerable insight into and improvement in the management and outcomes of acute aortic dissection. More information about IRAD can be found at www.iradonline.org.

B. Etiology and pathology

1. **Aortic dissection classically occurs when a tear in the intima results in separation of the intima from the media (90% of cases), forming a false lumen within the aortic wall. Less commonly, rupture of the vasa vasorum within the aortic wall may result in separation of the intima and media, thereby causing dissection. In either case, acute aortic dissection results from a pathologic weakening of the aortic wall due to medial necrosis, atherosclerosis, or inflammation**. There are many risk factors for aortic dissection, although the most common is a history of systemic hypertension as evidenced in over 70% of cases. Younger patients suffering aortic dissection are more likely to have a genetic or morphologic risk factor, such as genetic syndromes associated with aortopathy, bicuspid aortic valve (BAV), or prior aortic surgery. The following list includes the most common conditions associated with aortic dissection:
   a. Increased age and uncontrolled hypertension are the two most common risk factors.
   b. Tobacco use, dyslipidemia, and cocaine use are important risk factors.
   c. Genetic diseases, especially Marfan, Loeys-Dietz, and vascular-type Ehlers-Danlos syndromes, are associated with aortic aneurysm and dissection.
   d. Familial thoracic aortic aneurysm (TAA) and dissection syndrome and other congenital anomalies associated with aortic aneurysm and dissection, including BAV and Turner syndrome.
   e. Inflammatory vasculitides, including Takayasu arteritis, Giant cell arteritis, and Behçet arteritis.
   f. Infections involving the periaortic tissue, as seen in prosthetic aortic valve endocarditis.

g. Aortic trauma, particularly with deceleration and torsional injuries, although may occur with direct endoluminal trauma during arterial catheterization or with cardiothoracic surgery.
h. Pregnancy.

2. **Genetic syndromes associated with aortic aneurysm and dissection.** Marfan, Ehlers-Danlos, and Loeys-Dietz syndromes are associated with an increased risk of aortic dissection. **These patients require comprehensive aortic imaging at diagnosis and heightened surveillance to follow aortic diameter owing to the increased risk of complications related to aortic disease.** *Aortic imaging is recommended for first-degree relatives with TAA and/or dissection to identify those with asymptomatic disease (Level of Evidence: B).*
   a. **Marfan syndrome.** Marfan syndrome is a genetic disorder with high penetrance and variable expression affecting connective tissue. Marfan syndrome is associated with mutations of the *FBN1* gene, which encodes fibrillin-1, a large glycoprotein that contributes to the structure of the extracellular matrix and serves as a regulator of transforming growth factor-beta (TGF-β). The principal features of Marfan syndrome involve the cardiovascular, ocular, and skeletal systems, with patients at exceedingly high risk for aortic disease. In fact, nearly all patients with Marfan syndrome demonstrate some form of aortic disease during their lifetime.
   b. **Loeys-Dietz syndrome.** An autosomal dominant disorder associated with a triad of arterial tortuosity and aneurysm, hypertelorism, and bifid uvula, Loeys-Dietz syndrome results from mutations in either TGF-β receptor type 1 or 2 (*TGFBR1* or *TGFBR2*). Vascular disease among these patients is highly prevalent, with 98% demonstrating aortic root aneurysms, and portends a grim prognosis. Early reports of Loeys-Dietz syndrome suggested a particularly aggressive disease process with arterial complications occurring at a mean age of 26 years. However, subsequent data have revealed less aggressive phenotypes with later presentations, and a mean age of death closer to the fifth decade among less severe phenotypes. Repair of the aortic root is recommended at lesser aorta diameters (< 5.0 cm) due to the aggressive nature of this condition.
   c. **Ehlers-Danlos syndrome, type IV (vascular form).** The vascular form of Ehlers-Danlos syndrome is characterized by an autosomal dominant inheritance of the *COL3A1* gene mutation that encodes type III procollagen. Clinical features include easy bruising and rupture of the uterus, intestines, and arteries. Median survival is 48 years and often no aneurysms are documented. Gravid women with this condition have a particularly poor prognosis during childbirth due to the high risk of arterial and uterine rupture.

3. **Hereditary conditions and congenital anomalies** such as BAV and coarctation of the aorta are also established risk factors for aortic dissection. Turner syndrome is associated with BAV (10% to 25%), aortic coarctation (8%), and dilatation of the ascending aorta. Although patients with Turner syndrome require screening for aortic disease at diagnosis, requirements of surveillance for aortic dilatation follow those of other patients with BAV. *All patients with BAV should have both the aortic root and ascending aorta evaluated for evidence of aortic dilatation (Level of Evidence: B). First-degree relatives of patients with a BAV, premature onset of thoracic aortic disease with minimal risk factors, and/or a familial form of TAA or dissection should be evaluated for the presence of a BAV and asymptomatic thoracic aortic disease (Level of Evidence: C).*
4. **Vasculitides** associated with large vessel inflammation and aortitis contribute to medial degeneration of the aortic wall and may increase the risk of aortic dissection. Examples of these inflammatory disorders include giant cell arteritis, Takayasu arteritis, syphilis, and Behçet disease.

5. **Aortic dissection exhibits a strong association with pregnancy**. Among cases of aortic dissection in women < 40 years of age, up to half may present during the third trimester or early in the postpartum period. **Gravid women with Marfan syndrome and preexisting aortic root dilatation are at especially high risk for aortic dissection**.
6. **Direct aortic trauma is associated with aortic dissection**. Blunt chest trauma, such as that occurring in a motor vehicle accident, may cause aortic transection or mural hematoma. Intravascular instrumentation as during arterial catheterization, insertion of an intraaortic balloon pump, or aortic cannulation, cross-clamping, and graft insertion may also serve as a source of intimal damage and dissection.

C. Epidemiology. The incidence of aortic dissection has been estimated from 2 to 3.5 cases per 10,000 person-years, corresponding to 6,000 to 10,000 cases per year in the United States. The male-to-female ratio approaches 3:1, with the peak incidence in the sixth and seventh decades of life. The mortality for untreated acute aortic dissection is largely determined by the location of the dissection, but overall mortality is approximately 1% per hour within the first 48 hours if surgery is not performed. Approximately 65% of dissections originate in the ascending aorta (just above the right or noncoronary sinus), 20% in the descending thoracic aorta, 10% in the aortic arch, and the remainder in the abdominal aorta.

D. Classification schemes

1. **Anatomic classification schemes** used to commonly describe aortic dissection include the DeBakey and Stanford systems (see Table 26.1 and Fig. 26.1 for a description of the DeBakey and Stanford classifications). Anatomic classification refers to the portion(s) of aorta involved. The Stanford classification will be used throughout this chapter.
2. Dissections are further classified according to chronicity: acute (< 2 weeks from onset) or chronic (> 2 weeks from onset).
3. Anatomic involvement and chronicity of dissection influence the recommended treatment approach and indicate prognosis.
   a. **Type A dissection.** Predictors of death are age 70 years or older, abnormal electrocardiogram (ECG), pulse deficit, acute renal failure, and the composite of hypotension, shock, or tamponade.
   b. **Type B dissection.** Predictors of death are branch vessel involvement, absence of chest or back pain, and hypotension/shock. Continued patency of the false lumen predicts a worse outcome in type B aortic dissection. The highest survival benefit is among those with complete thrombosis of the false lumen.

TABLE 26.1 Aortic Dissection Classification Systems

Classification	Pathologic description
Stanford	
Type A	Any dissection involving the ascending aorta
Type B	Any dissections *not* involving the ascending aorta
DeBakey	
Type I	Entry point in the ascending aorta, extends to the aortic arch and often beyond
Type II	Confined entirely to the ascending aorta
Type III	Entry in the descending aorta (distal to left subclavian); extends distally (usually) or proximally (rarely)

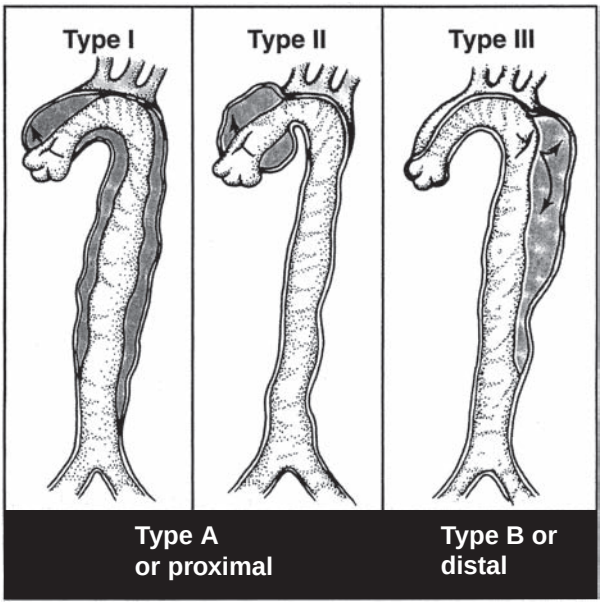

FIGURE 26.1 Anatomic appearance of three different aortic dissection classifications.

E. Atypical variants of aortic dissection

1. **IMH** represents a focal hemorrhage of the aortic wall caused by rupture of the vasa vasorum within the aortic wall and may cause secondary dissection. The natural history of IMH is similar to that of classic aortic dissection. In fact, in 4% to 10% of dissections, an intimal tear is not found. Therefore, *it is reasonable to treat IMH similar to de facto aortic dissection including surgery if located in the ascending aorta or aggressive medical therapy if in the descending aorta (Level of Evidence: C).*
2. **PAU** is a focal defect in the endoluminal surface of the aortic wall produced by atherosclerotic erosion through the intima with ulceration into the media. Risk factors for PAU include older age, extensive atherosclerosis, and uncontrolled hypertension. PAU may manifest as subtle asymptomatic erosions noted incidentally on radiography to symptomatic IMH with eccentric or saccular aneurysms of the aorta. In either case, PAU may progress to aortic dissection or aortic perforation, although the natural history of this condition remains uncertain. Nevertheless, surgery is often recommended for patients exhibiting unstable symptoms or lesions involving the ascending aorta. Otherwise, medical management and frequent radiologic follow-up for signs of progression is recommended.

F. Clinical presentation

1. **Signs and symptoms**
   a. Aortic dissection may present with a wide range of clinical manifestations. Proximal dissections are most commonly characterized by a sudden onset of chest pain (80%) that is severe in intensity and ripping, tearing, stabbing, or sharp in quality. Pain may radiate to the interscapular region of the back (47%) or abdomen (21%). Among descending aortic dissections, back pain (64%), chest pain (63%), and abdominal pain (43%) are most common. **Typical symptoms are less common in the elderly**.

b. Presenting clinical findings may include the murmur of severe aortic insufficiency (AI) (45%) associated with proximal aortic dissection and contributing to acute heart failure (5% to 6%), hypotension (14%) or shock (13%) associated with cardiac tamponade (5% to 10%), syncope (13%), myocardial infarction (MI) (7% to 19%) with retrograde dissection into the ostia of the coronary arteries, cardiovascular accident (CVA) (8%) with cephalad carotid extension, paraplegia (2%) with extension into the intercostal and spinal arteries, or cardiac arrest. Dissections involving the arterial supply to the limbs may contribute to pulse deficits (26%), acute limb ischemia (10%) with distal extension, and neuropathy.

G. Diagnostic testing

1. **Evaluation.** Figure 26.2 provides an algorithm to aid in diagnosis. Key characteristics important in defining the extent of aortic dissection and clinical management include ascending versus descending aortic involvement, site of the intimal tear, presence or absence of AI, presence of pericardial effusion and/or tamponade, coronary involvement, and involvement of visceral arterial supply. Computed tomography (CT), magnetic resonance imaging (MRI), transesophageal echocardiography (TEE), and invasive aortography are common imaging modalities useful in the diagnosis of acute aortic dissection. The relative advantages and disadvantages of the four modalities are outlined in Table 26.2. **Selection of the specific imaging modality for identification or exclusion of aortic dissection should be based on clinical variables, local expertise, and clinical availability to facilitate rapid diagnosis (Level of Evidence: C)**.
2. *An ECG should be performed in all patients with suspected aortic dissection (Level of Evidence: B).* Most frequently, ECG is useful to exclude an acute coronary syndrome presenting atypically as symptoms of aortic dissection. *Because dissection-related acute MI is infrequent, ST-segment elevation on ECG should be treated as an independent coronary event without delay for aortic imaging unless the patient is at high risk for aortic dissection (Level of Evidence: B).*

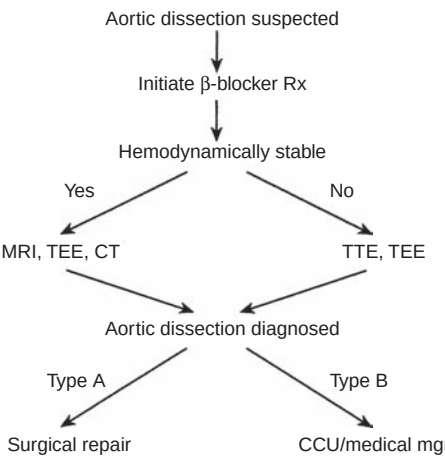

FIGURE 26.2 Aortic dissection diagnostic/therapeutic algorithm. CCU, coronary care unit; CT, computed tomography; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

TABLE 26.2 Comparison of Imaging Modalities in Aortic Dissection

Factor	Angiography	CT	MRI	TEE
Intimal tear definition	++	+++	+++	++
False lumen thrombus +/–	+++	+++	+++	+
Involvement of branch vessels	+++	++	++	+
Pericardial effusion	–	+++	+++	+++
Coronary involvement	+++	–	–	++
AI presence	+++	–	+	+++
Overall sensitivity (%)	88	100	98	98
Overall specificity (%)	95	98	98	95

AI, aortic insufficiency; CT, computed tomography; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography.

Modified from Isselbacher EM, Eagle RA, DeSanctis RW. Diseases of the aorta. In: Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine.* 5th ed. Philadelphia, PA: WB Saunders, 1997:1546–1581.

3. Chest radiography may occasionally detect findings suggestive of dissection, although it is inadequately sensitive to definitively exclude the presence of acute aortic dissection. *A negative chest x-ray should not delay definitive aortic imaging in patients determined to be high risk for aortic dissection by initial screening (class III recommendation, Level of Evidence: C).*

H. Selected imaging modalities for diagnosis of acute aortic dissection

1. **Computed tomography.** Contrast-enhanced, cardiac-gated multidetector CT is a widely available and the most commonly used imaging modality for the detection of aortic dissection, with excellent sensitivity and specificity approaching 100%. This modality has many advantages, including rapid scan and interpretation times. Disadvantages include iodinated contrast and radiation exposure.
2. **MRI and magnetic resonance angiography (MRA).** Like CT, MRI provides multiplanar imaging of the thoracic aorta with high sensitivity and specificity that is very accurate for diagnosis of acute aortic disease. MRA offers unique gadolinium-enhanced and black blood imaging techniques to evaluate aortic anatomy and morphology that prove particularly useful in assessing the aortic wall. Advantages of MRI include the ability to identify anatomic variants, such as IMH or penetrating aortic ulcer, assess branch arterial involvement, and provide useful information on aortic valvular and left ventricular systolic function while avoiding exposure to iodinated contrast or radiation. MRI is well suited for chronic follow-up of aortic syndromes since ionizing radiation is not necessary. Use of MRI is limited by availability, prolonged acquisition time, and incompatibility with implanted ferromagnetic devices. MRI is not an appropriate test for patients that are hemodynamically unstable.
3. **Transthoracic echocardiography (TTE) and TEE.** TTE allows for a rapid noninvasive evaluation, primarily of the proximal aorta with overall limited sensitivity and specificity. Visualization of the proximal aorta and other critical structures using TTE may be limited by factors that reduce image quality, such as emphysema, mechanical ventilation, and obesity. With an esophageal approach, TEE overcomes many of the challenges with improved sensitivity and specificity while offering a safe and rapid assessment of acute aortic disease. A major limitation of either TTE or TEE includes the appearance of ultrasound artifacts that may mimic a dissection flap, such as that of reverberation artifact.

4. **Invasive aortography.** Aortography offers accurate information about the location of dissection, providing visualization of the false lumen or intimal flap, branch vessel involvement, and communication between true and false lumens. Invasive aortography is useful in evaluating PAU, as it is characterized by endovascular aortic contrast protruding into an atherosclerotic plaque. False negatives can occur with thrombosis of the false lumen, IMH, or equal filling of the false lumen. Disadvantages or aortography include a low sensitivity, risks associated with any invasive procedure, contrast administration, and availability of experienced operators to perform the study.
5. **Recommendations for aortic imaging techniques to determine the presence and progression of thoracic aortic disease**
   a. *Measurements of aortic diameter should be taken at reproducible anatomic landmarks, perpendicular to the axis of blood flow, and reported in a clear and consistent format (Level of Evidence: C).*
   b. *For measurements taken by CT imaging or MRI, the external diameter should be measured perpendicular to the axis of blood flow. For aortic root measurements, the widest diameter, typically at the mid-sinus level, should be used (Level of Evidence: C).*
   c. *For measurements taken by echocardiography, the internal diameter should be measured perpendicular to the axis of blood flow. For aortic root measurements, the widest diameter, typically at the mid-sinus level, should be used (Level of Evidence: C).*
   d. *Abnormalities of aortic morphology should be recognized and reported separately even when aortic diameters are within normal limits (Level of Evidence: C).*
   e. *The finding of aortic dissection, aneurysm, traumatic injury and/or aortic rupture should be immediately communicated to the referring physician (Level of Evidence: C).*
   f. *Techniques to minimize episodic and cumulative radiation exposure should be utilized whenever possible (Level of Evidence: B).*

I. Therapy. Death in aortic dissection results from vascular compromise, tamponade, or aortic rupture. ***Management of proximal (type A) thoracic aortic dissection requires immediate surgical treatment to resect the entire aneurysmal aortic segment and the proximal extent of dissection (Level of Evidence: C).*** Surgery greatly improves outcomes and avoids the risks associated with progression of dissection. One- and three-year survival after surgery for type A dissection is excellent, with survival rates of 96.1% and 90.5%, respectively. Survival rates at 1 and 3 years are 88.6% and 68.7%, respectively, among those who do not receive surgery for type A dissection. ***Patients with distal (type B) thoracic and abdominal aortic dissections should be managed medically unless life-threatening complications, such as malperfusion syndromes, progression of dissection, aortic enlargement, or refractory hypertension, develop (Level of Evidence: B).*** **Percutaneous endovascular aortic repair (EVAR)** is a technically feasible and potentially effective option for nonsurgical treatment of type B aortic dissection, although it has not been approved by the Food and Drug Administration (FDA) for this indication. Table 26.3 recommends the course of treatment for various types of dissections. The 5-year survival rate for patients leaving the hospital with appropriate treatment (medical or surgical) for type B dissection ranges from 75% to 82%.

1. **Priority of therapy.** The initial management of patients with suspected aortic dissection is directed at **reducing aortic wall stress. Aortic wall stress is affected by the velocity of ventricular contraction (dP/dt), the rate of ventricular contraction, and blood pressure. Medical stabilization of acute aortic dissection should target the reduction of heart rate followed by lowering of blood pressure**. Invasive hemodynamic monitoring and sufficient intravenous access for volume replacement should be established simultaneously. An

TABLE 26.3 Surgical versus Medical Therapy for Aortic Dissection

Medical therapy	Surgical therapy	Endovascular therapy
Uncomplicated type B dissection	Acute, type A dissection	Malperfusion syndrome associated with type B dissection
Stable, lone arch dissection	Acute, complicated type B dissection	Possibly as an alternative to surgical therapy for complicated type B dissection
Stable, chronic type B dissection (> 2 wk after onset of symptoms)	End-organ dysfunction	Possibly as an alternative to medical treatment for uncomplicated type B dissection
	Rupture/impending rupture Aortic insufficiency Associated with Marfan syndrome Retrograde extension into the ascending aorta	

initial and aggressive treatment approach to reduce d*P*/d*t* applies to all patients regardless of the location of dissection or whether the eventual management strategy is medical or surgical.

2. **Medical therapy** (see Table 26.4)
   a. ***With suspicion of acute aortic dissection, β-blockers should be initiated immediately and titrated to target heart rate of < 60 beats per minute***

TABLE 26.4 Intravenous Dosing for Acute Medical Management of Acute Aortic Syndromes

Drugs	Loading dose	Maintenance dose
First-line agents		
Propranolol	1 mg IV q3-5min (max. 6.15 mg/kg)	2–6 mg IV q4-6h
Labetalol	10 mg IV over 2 min, then 20–80 mg q10-15min (max 300 mg)	2 mg/min IV drip titrate to 5–20 mg/min
Esmolol	500 μg/kg IV bolus	50–200 μg/kg/min IV continuous
Metoprolol	5 mg IV q5min to effect	5–10 mg IV q4-6h to effect
Second-line agents in patients with contraindications for β-blockers		
Enalaprilat	0.625 mg IV	0.625 mg IV q4-6h
Diltiazem	0.25 mg/kg IV over 2 min; 0.35 mg/kg IV after 15 min if no effect	5 mg/h titrate by 2.5 to 5 mg/h increments; max 15 mg/h
Verapamil	0.075–0.1 mg/kg to 2.5–5 mg/kg over 2 min	5 to 15 mg/h IV drip

IV, intravenous.

(Level of Evidence: C). In patients who are intolerant of β-blockers, nondihydropyridine calcium channel blockers may serve as an acceptable alternative to control heart rate (see Table 26.4) (*Level of Evidence: C). In the setting of acute aortic regurgitation, use of rate-controlling agents, such as β-blockers, should be used with caution since they block compensatory tachycardia (Level of Evidence: C).*

b. *Once the heart rate goal has been achieved, systolic blood pressure should be targeted to < 120 mm Hg with the use of angiotensin-converting enzyme inhibitors or vasodilators to reduce blood pressure while maintaining adequate end-organ perfusion* (*Level of Evidence: C)*. With a goal of heart rate and blood pressure control, β-blockers with α-effect, such as labetalol, may be particularly advantageous. Sodium nitroprusside is a particularly useful vasodilator, given a rapid onset and easy titration as an intravenous infusion. Close monitoring for reflex tachycardia should be done with use of vasodilators—*vasodilator therapy should not be initiated prior to heart rate control since reflex tachycardia may increase aortic wall stress and risk of propagation or expansion of dissection (class III, Level of Evidence: C).*

3. Managing complications of acute aortic dissection

a. Hypotension and shock. Aortic wall rupture or hemorrhage into the pericardial space with cardiac tamponade may manifest as shock. In either event, **aggressive volume replacement should be initiated and the patient taken to the operating room promptly**. Pericardiocentesis is generally not recommended. If pericardiocentesis becomes an absolute requirement to get the patient to the operating room, enough pericardial fluid should be removed to raise the blood pressure to an acceptable level, but no more. **If vasopressors are required for hemodynamic stabilization, norepinephrine and phenylephrine are the drugs of choice, as neither has a demonstrable effect on d*P*/d*t*. Epinephrine and dopamine should be avoided.**

b. Acute MI. Coronary thromboembolism and retrograde progression of the aortic dissection flap into the coronary ostia are infrequent complications of proximal aortic dissection. In this setting, **thrombolysis is contraindicated**. Coronary arteriography and percutaneous intervention are not generally recommended since these procedures will **delay surgical repair of the dissection while exposing it to mechanical complications related to angiography in an already compromised aorta**.

c. Refractory hypertension. Sufficient blood pressure reduction can be difficult to obtain, with many patients requiring several antihypertensive drugs of different classes. Adequate analgesia is essential to reduce pain-related increases in sympathetic tone and blood pressure associated with acute aortic dissection. Following initial stabilization, use of β-blockers should be continued with consideration for angiotensin-converting enzyme inhibitors or angiotensin receptor antagonists that may slow pathologic aortic dilatation.

4. Surgical management of acute aortic dissection

a. *Patients with a proximal (type A) thoracic aortic dissection should receive emergent surgery. A partially dissected aortic root with a normal aortic valve may be repaired with supracommissural aortic valve resuspension. In the event that the aortic valve cannot be repaired or resuspended, a Bentall procedure may be performed with a prosthetic valve sewn onto a Dacron graft and used to replace the native valve with reimplantation of the coronary arteries into the graft (Level of Evidence: C).*

b. *Patients with type B dissection who have evidence of rupture or end-organ involvement should receive surgical repair with replacement of the entire segment of dissected aorta (Level of Evidence: C).* Reattachment of the visceral arteries and T_8 to L_2 intercostal/lumbar arteries are implanted into the graft conduit.

c. Perioperative risk. Compared with unstable patients with aortic dissection, those demonstrating preoperative stability have an improved prognosis.

Nevertheless, stable patients still carry a substantial surgical mortality of 17%. When patients have features of instability—such as cardiac tamponade, shock, congestive heart failure (CHF), cerebrovascular accident, coma, MI, acute renal failure, or mesenteric ischemia—surgical mortality rates rise to approximately 31%. Surgical mortality increases with age. However, the relative benefits of surgery outweigh risks of nonoperated type A dissection until at least the age of 80 years. Therefore, the benefits of surgery should be measured against surgical risks of all age groups, with consideration for complexity of repair, preoperative medical comorbidities, and anticipated quality of life after surgery.

d. Postsurgical complications of open thoracic surgical repair include respiratory failure (5% to 15%), stroke (2% to 8%), bleeding requiring reoperation (1% to 6%), infection (1% to 5%), MI (1% to 5%), heart failure (1% to 5%), ventricular arrhythmias (1% to 5%), acute postoperative renal failure, paraplegia (2% to 10%), and mesenteric ischemia.

(1) *A brain-protective strategy to prevent stroke and preserve cognitive function should be a key element of the surgical, anesthetic, and perfusion techniques used to accomplish repairs of the ascending aorta and aortic arch (Level of Evidence: B).*

(2) Paraplegia stands among the most feared complications of descending thoracic and thoracoabdominal aortic repairs, occurring in 2% to 4% and 3% to 10% of cases, respectively. Paraplegia results from the disruption of blood flow to the anterior spinal artery via the intercostal arteries. *Cerebrospinal fluid drainage is recommended as a spinal-protective strategy in open and endovascular thoracic aortic repair for patients at high risk for spinal cord ischemic injury (Level of Evidence: B).*

5. Percutaneous EVAR for type B aortic dissection. EVAR represents a technically feasible and potentially effective option for nonsurgical treatment of type B aortic dissection, although it has not received FDA approval for this indication and such use is considered "off-label." Nevertheless, stent-grafting for conditions other than abdominal aortic aneurysm (AAA) is an area of active study, with proposed uses for EVAR in stable type B aortic dissection, IMH, PAU, acute traumatic aortic transection, and pseudoaneurysm.

a. Potential advantages of EVAR over conventional surgery include the absence of thoracotomy, avoiding cardiopulmonary bypass and clamping of the aorta, lower hospital morbidity rates, and shorter length of hospital stays. A mortality advantage of endovascular therapy was suggested in early trial reports, although it has largely been lost with longer-term follow-up from these studies.

b. Comparing EVAR with optimal medical management (OMM). Although OMM remains the mainstay for acute treatment of uncomplicated type B dissection, long-term morbidity and mortality of chronic dissection remain substantial. Data on EVAR for use in descending aortic dissection are limited. Results from a meta-analysis of 609 cases suggest that mortality rates are higher with EVAR (5.3%) compared with open surgical correction (2.5%), although the risk of major complications with either treatment is similar. Two prospective randomized trials have compared endovascular repair with OMM.

(1) The prospective INvestigation of STEnt grafts in patients with type B Aortic Dissection (INSTEAD) trial provided the first randomized evaluation of elective stent-graft placement in 140 patients with subacute or chronic uncomplicated type B aortic dissection. INSTEAD did not show a 2-year survival advantage or difference in adverse event rates with EVAR compared with optimal medical therapy.

(2) The optimal timing of EVAR for aortic dissection remains to be defined. The Acute Dissection Stent-grafting OR Best Medical Treatment

(ADSORB) trial is an ongoing study poised to compare EVAR with OMM for *acute* uncomplicated type B aortic dissection. Target enrollment is 250 patients with 3-year follow-up. Study completion is anticipated in 2015.

6. **Postoperative surveillance after thoracic aortic repair or monitoring of chronic descending aortic dissection**
   - **a.** *CT or MRI of the thoracic aorta is reasonable after type A or type B aortic dissection or after prophylactic repair of the aortic root/ascending aorta (class IIa, Level of Evidence: C).*
   - **b.** *CT or MRI of the aorta is reasonable at 1, 3, 6, and 12 months after dissection, then annually thereafter if clinically stable (class IIa, Level of Evidence: C).* In about 30% of cases, late deaths are caused by rupture of a secondary aneurysm or recurrence of the dissection. A majority of these secondary aneurysms will develop within 2 years of the initial treatment.
   - **c.** *For patients with chronic dissection, particularly if associated with a connective tissue disorder, but without significant comorbid disease, and a descending thoracic aortic diameter exceeding 5.5 cm, open repair is recommended* (*Level of Evidence: B).*
   - **d.** *Long-term, aggressive cardiovascular risk factor management is critical before and after thoracic aortic surgery and includes aggressive heart rate and blood pressure control to reduce dP/dt, lipid profile optimization, and smoking cessation (Level of Evidence: C).* In the event of medical treatment failure, including end-organ damage related to complications of aortic disease, aortic leak, or escalating visceral pain, patients with chronic descending aortic dissection should be considered for surgical treatment.

III. AORTIC ANEURYSM. An aortic aneurysm is a pathologic dilatation of the aorta to > 1.5 times its normal diameter. Aneurysms are classified based on involvement of the anatomic aortic segment, including AAA and TAA. The etiology, natural history, and treatments differ somewhat for aneurysms of each location.

A. Abdominal aortic aneurysm. Aneurysms of the aorta located below the diaphragmatic crura and above the bifurcation of the common iliac arteries are classified as AAA.

1. **Etiology and pathology of aortic aneurysm**
   - **a. Aneurysms of the aorta are caused by degenerative disease within the aortic wall, leading to inflammation, weakening of the aortic tissues, loss of elasticity, and dilatation of the aorta.** Atherosclerosis has traditionally been linked with development of AAA, although the pathogenesis is likely multifactorial, involving immunologic, genetic, environmental, and hemodynamic factors. Matrix metalloproteinases and other proteases produced locally by smooth muscle cells may degrade elastin and collagen and lead to aneurysm formation.
   - **b. Genealogic studies demonstrate a strong familial component to developing AAA**, with up to 28% of patients having a first-degree relative with an abdominal aneurysm. First-degree male relatives of patients with AAA have a 12 times greater risk of having an aneurysm.
   - **c. Risk factors for the development of AAA** include current or past history of tobacco use, male gender, advanced age, first-degree relative with AAA, hypertension, hyperlipidemia, and atherosclerosis in other vascular beds. Less common causes include infection (*Salmonella* and *Staphylococcus aureus*), *vasculitis*, and trauma.
   - **d. Rate of enlargement is dependent on aneurysmal diameter.**
     - **(1)** Rate of enlargement can range from 0.2 cm/y to > 3 cm/y. The majority of aneurysms enlarge at a rate of 2.6 mm/y. **The larger the aneurysm grows, the faster it will continue to expand.**

(2) Laplace's law defines the parameters for growth of aneurysms.

Wall tension = transmural pressure (TP) × radius (*r*)

(1) Therefore, with luminal dilatation (increased *r*), the wall tension will increase at a given blood pressure (TP). This leads to a further increase in radius and to a self-perpetuating cycle of growth of the aneurysm.

e. Characteristics of aneurysmal rupture:

(1) *Risk is proportional to aneurysm size*. Aneurysms > 6.0 cm have > 20% per year risk of rupture, whereas those between 5 and 6 cm have approximately 6% risk of rupture per year.

(2) Rupture usually occurs into the left retroperitoneal space (80%). Rupture in this location may initially be contained, although it will ultimately extend, causing shock and death if untreated.

(3) AAA can also rupture into the inferior vena cava (causing aortovenous fistula formation). Fistulous connection between an enlarging aortic aneurysm and the gastrointestinal tract may create an aortoenteric fistula that may present as a life-threatening emergency requiring prompt surgical intervention. A **gastrointestinal bleed with known AAA or history of AAA repair should prompt consideration for an aortoenteric fistula**.

(4) **Rupture of an AAA is associated with high mortality**. One-quarter of patients with rupture die before reaching the hospital and 50% die prior to undergoing surgery. Among those who survive to undergo surgery, the operative mortality approaches 50%.

2. Epidemiology

a. AAA is much more common than TAA, as nearly 75% of aneurysms involve the abdominal aorta.

b. AAA affects men more commonly than women. Among patients over age 65 years, the prevalence of AAA among men and women is 5% and 1.0% to 2.2%, respectively. The incidence of AAA increases after age 55 years in men and 70 years in women. Most cases (95%) involve the infrarenal aorta.

3. Clinical presentation. The majority of AAAs are discovered incidentally on physical examination or during radiologic evaluation of the abdomen.

a. Signs and symptoms. Most patients are asymptomatic; therefore, the diagnosis of AAA should be considered in patients with an appropriate risk profile and family history.

(1) Rapid enlargement of the aneurysm may be associated with severe back or flank pain and herald impending rupture. Pain associated with an expanding AAA is described as sudden in onset, constant, and not affected by movement or position. Occasionally, there is radiation to the legs, buttocks, or groin.

(2) Findings consistent with shock (hypotension, pallor, diaphoresis, oliguria, and obtundation) can develop rapidly with a ruptured aneurysm.

b. Physical findings

(1) A palpable, pulsatile mass may be felt on abdominal examination and may extend variably from the xiphoid process to below the umbilicus, although accurate sizing is nearly impossible on physical examination. Palpation should be gentle or potentially avoided, especially if the aneurysm is tender, as tenderness can be an indication of impending rupture.

(2) Associated vascular disease is common among those with AAA and may be represented by abdominal or femoral bruits or decreased pulses in the extremities.

(3) Examination findings of distal thromboembolism may be noted in the distal extremities and represent atheromatous material or mural

thrombus with embolism. Other related findings may include livedo reticularis, painful blue toes, hypertension, and acute kidney injury.

4. **Diagnostic testing**
   a. **Abdominal ultrasound** is the most commonly used screening tool for AAA. Aortic ultrasound has the capacity to obtain both longitudinal and transverse images of the aneurysm and has been validated to accurately measure size to within ±0.3 cm. **Major advantages of ultrasound include its wide availability, cost-effectiveness as a diagnostic and screening imaging technique, and avoidance of ionizing radiation exposure**. If imaging is adequate, ultrasound is an effective option when monitoring aneurysm growth serially. Disadvantages of abdominal ultrasound include poor definition of branch vessels; therefore, ultrasound is insufficient for preoperative evaluation.
   b. **CT aortography** with cardiac gating allows for accurate evaluation of the aneurysm shape, and volumetric acquisition provides detailed three-dimensional analysis of spatial relations to branch vessels and diagnosis of associated acute aortopathies including PAU. CT measurements have been validated to within ±0.2 cm. CT offers an advantage of evaluating for extravasated blood in acute or subacute rupture. The major disadvantages of CT include the requirement for ionizing radiation and intravenous contrast, which limit its utility in follow-up of chronic aortic dissection (see Chapter 52).
   c. **MRI** provides excellent definition of aneurysm size as well as suprarenal and iliofemoral extension. MRA allows for improved visualization of compromised flow to branch vessels, although it lacks sensitivity to absolutely define obstruction in the renal vessels. MRI is disadvantaged by cost and limited availability.
   d. **Aortography** effectively defines both suprarenal and iliofemoral involvement as well as branch vessel impingement, although it tends to underestimate the size, especially when mural thrombus is present. Compared with other techniques, aortography is invasive and requires the use of intravenous contrast and ionizing radiation. Aortography is now generally reserved for planning endografting in some centers and is less useful as an initial diagnostic modality.

5. **Therapy**
   a. **Medical therapy**
      (1) β-Blockers have been shown to decrease the rate of enlargement and risk of rupture in at least one clinical trial (Gadowski et al., *J Vasc Surg.* 1994), although other studies have not confirmed this effect.
      (2) Aggressive risk factor modification with control of hypertension and hypercholesterolemia is **imperative to prevent adverse events from atherosclerotic disease in other vascular beds. Smoking cessation should be strongly advocated**.
      (3) Serial ultrasound or CT scanning is indicated in patients without symptoms that have aortic diameters of 2.5 cm or greater. Studies should be obtained yearly when the aortic diameter reaches 3.0 cm, every 6 months for dimensions between 4 and 5 cm, and every 3 to 6 months for aneurysms between 5.0 and 5.5 cm not surgically repaired. Ultrasound is generally preferred for surveillance of small AAAs, owing to lack of radiation exposure.
   b. **Endovascular aortic repair.** Percutaneous aortic stent-grafting has been FDA-approved for use in descending thoracic aortic or infrarenal AAA. Endovascular grafting is a less invasive option for the repair of AAA and is especially appealing for elderly patients or those with substantial cardiac, pulmonary, and renal dysfunction.
      (1) **The EVAR procedure.** Under fluoroscopic guidance, the proximal and distal ends of the stent-graft are affixed to normal segments of the aorta above and below the aneurysmal portion, thereby sealing off the

aneurysm. **Suitable anatomy is necessary for stent-grafting.** Favorable characteristics for EVAR include normal diameter of aorta distal to the renal arteries and proximal to the aneurysmal segment, minimal angulation, freedom from severe obstructive lesions, and patency of side branches and distal iliac vessels. Only 30% to 60% of patients will have anatomy suitable for endovascular repair.

(2) **Comparing EVAR with open surgical repair.** Several randomized trials have compared endovascular repair with open surgical repair, including the Dutch Randomized Endovascular Aneurysm Management (DREAM) trial, the Endovascular Aneurysm Repair 1 (EVAR-1) trial, and the Open Versus Endovascular Repair (OVER) Veterans Affairs Cooperative trial, among others. Six years after randomization, patients in the DREAM trial received no survival benefit after EVAR compared with those undergoing conventional surgery. Similarly, patients followed to a median of 6 years in the EVAR-1 trial enjoyed a lower operative mortality with endovascular repair over open repair, although no differences were seen in total mortality or aneurysm-related mortality in the long term. As techniques improve, so too may postoperative outcomes among patients randomized to endovascular versus open AAA repair. An interim report from the most contemporary OVER Veterans Affairs Cooperative trial has concluded that early operative advantages of EVAR have not yet been offset by increased morbidity and mortality in the first 2 years after aortic repair. Further comparisons of outcome data from this and other ongoing trials will continue to provide appraisal of the long-term clinical benefits and cost-effectiveness of this technique compared with conventional therapy.

(3) **EVAR among unsuitable surgical candidates.** Compassionate use of EVAR among patients for whom open repair is deemed too high risk because of medical comorbidities was studied in the Endovascular Aneurysm Repair 2 (EVAR-2) trial. This study failed to show any survival benefit with endovascular repair—a disappointing finding as the clearest indication for endovascular repair was traditionally thought to be for those at high risk for open repair.

(4) **Endoleak as a complication of EVAR.** One of the common complications of endovascular repair is endoleak (Table 26.5). Endoleak represents a failure of the stent-graft to completely exclude the aneurysm and

TABLE 26.5 Classification of Endoleaks

Endoleak type	Cause of leak about graft
I	Inadequate seal at proximal and/or distal graft attachment
II	Retrograde arterial flow into the aneurysm sac from an aortic arterial branch within the stented segment
III	Structural failure of the graft material (e.g., graft tear or hole, stent fracture)
IV	Stent-graft porosity
V	Aneurysmal expansion without demonstrable endoleak ("endotension")

Modified from Hiratzka, LF, Bakris GL, Beckman JA, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. *J Am Coll Cardiol.* 2010;55(14):e27–e129.

results in persistent flow into the aneurysm, thereby increasing the risk of aneurysm expansion and rupture. Endoleaks occur in 10% to 20% of cases and are associated with more frequent reinterventions than open repair and the requirement of lifelong periodic follow-up imaging.

(5) **Other complications related to EVAR** include endograft migration, prosthesis infection, vascular access site-related infections, bleeding, thromboembolism, and spinal cord ischemia with paraplegia.

(6) *Periodic long-term surveillance imaging should be performed to monitor for endoleak, confirm graft position, document shrinkage or stability of the excluded aneurysm sac, and determine the need for further intervention in patients who have undergone endovascular repair of infrarenal aortic and/or iliac aneurysms (Level of Evidence: A).*

c. **Surgical therapy.** Surgical repair generally requires resection of the aneurysmal segment, with replacement using a Dacron tube graft inserted in place of the diseased aorta. The major branches are then reimplanted to the graft.

(1) **Preoperative evaluation.** Given the strong association of coronary artery disease with AAA and high operative mortality with untreated severe coronary artery disease, **all patients being considered for surgical repair of AAA require preoperative cardiac risk assessment**. Perioperative mortality in elective procedures is 4% to 6% (< 2% in low-risk patients).

(2) **Repair of AAAs < 5.0 cm in diameter provides no long-term survival benefit.** Controversy remains regarding medical versus surgical management of aneurysms between 5.0 and 5.5 cm and so should be managed on a case-by-case basis. **Surgery is indicated for an aneurysm with diameter measuring 5.5 cm or if rapidly expanding (> 1 cm/y)**. Women have a higher overall risk of rupture and tend to rupture at smaller aortic diameters compared with males. Therefore, it is the recommendation of some vascular societies that women should undergo elective repair at aortic diameters 4.5 to 5.0 cm. Symptomatic patients should also be referred for repair.

B. Thoracic aortic aneurysm. Thoracic aneurysms include those that involve the aorta from the level of the aortic root to the diaphragmatic crura. Extension of a descending thoracic aneurysm below the diaphragm creates a thoracoabdominal aneurysm.

1. **Clinical presentation.** Most patients with thoracic aneurysm are asymptomatic at the time of diagnosis, and the condition is often discovered as an incidental finding on imaging done for other reasons.

a. **Signs and symptoms**

(1) **Vascular complications of the aneurysm** include AI with left ventricular dilatation and CHF, myocardial ischemia due to coronary artery compression, sinus of Valsalva rupture into the right atrium/ventricle with left-to-right shunt and CHF, or thromboembolic phenomena.

(2) **Compression of external structures by the aneurysm** causes superior vena cava syndrome, dysphagia from esophageal compression, or hoarseness from recurrent laryngeal nerve compression. In addition, compression of the trachea or mainstem bronchus can lead to wheezing, dyspnea, tracheal shift, cough, or hemoptysis. Chest or back pain from compression and bony involvement is described as constant, boring, and deep.

(3) **Rupture** presents with sudden, severe, sharp chest or back pain. In order of decreasing frequency, TAAs rupture into the left pleural space, the pericardium (presenting as tamponade), and the esophagus (presenting as hematemesis).

(4) **Aortic dissection.** See Section III.

b. Physical examination. Specific physical findings directly attributable to TAA **are usually absent**.

(1) Cardiac. The diastolic murmur of AI (classically right lower sternal border) and a laterally displaced point of maximum impulse are sometimes noted with chronic ascending aortic dilatation. Signs of CHF can be seen in these circumstances. Unilateral jugular venous distention can be seen in patients with venous compression.

(2) Vascular. Rarely, a pulsatile mass can be palpated in the suprasternal notch. Differential pulses in the extremities can sometimes be found. Evidence of thromboembolic events can be seen upon examination of the digits. If the aneurysm compresses the venous return, evidence of superior vena cava syndrome or lower extremity edema may be found.

(3) Pulmonary. If the aneurysm compresses part of the bronchial tree, decreased air movement or stridor is auscultated.

2. Etiology

a. Table 26.6 gives the various classifications of TAAs as well as the segment involved and pathophysiology. The most common cause of TAA formation is medial necrosis, characterized by loss of elastic fibers and smooth muscle within the aortic media with replacement of tissue with interstitial cysts of basophilic ground substance leading to a cystic appearance.

b. Approximately 5% to 10% of patients undergoing surgery for AI are secondary to **annuloaortic ectasia**, which is a variant of cystic medial necrosis. Annuloaortic ectasia is a clinicopathologic diagnosis in which the aortic root, ascending aorta, and aortic annulus dilate, resulting in AI. This is more common in men and is typically seen in the fourth, fifth, and sixth decades of life.

3. Clinical course and surgical recommendations for asymptomatic TAA

a. Onset of symptoms usually heralds a more rapid course, as do larger dimensions at baseline. *Patients with symptoms suggestive of expansion of a TAA should be evaluated for prompt surgical intervention unless life expectancy from comorbid conditions is limited or quality of life is substantially impaired (Level of Evidence: C).*

b. Rupture is the most common cause of death in these patients. Data from the Yale group found that median size at rupture for an ascending aortic aneurysm was 6.0 cm and for a descending aortic aneurysm it was 7.2 cm. ***Asymptomatic patients should be evaluated for surgical repair*** *who have degenerative TAA, IMH, PAU, mycotic aneurysm, or pseudoaneurysm, who are otherwise suitable candidates and* ***for whom the ascending aorta or diameter of the aortic sinuses is 5.5 cm or greater*** *(Level of Evidence: C).*

c. TAAs tend to grow more rapidly as they increase in size and thereby increase the risk of acute rupture or dissection. Aneurysms < 5.0 cm at baseline have a mean growth rate of 0.17 cm/y, whereas those > 5.0 cm grew at a mean rate of 0.79 cm/y. ***Patients with a growth rate > 0.5 cm/y in an aorta that is < 5.5 cm in diameter should be considered for operation*** *(Level of Evidence: C).*

d. *Patients undergoing aortic valve repair or replacement who also have an ascending aorta or aortic root diameter > 4.5 cm should be considered for concomitant repair of the aortic root or replacement of the ascending aorta (Level of Evidence: C).*

e. *Patients with Marfan, Loeys-Dietz, or vascular-type Ehlers-Danlos syndrome or other genetically mediated disorders (BAV, Turner syndrome, and familial TAA and dissection) should undergo elective operation at smaller diameters (4.0 to 5.0 cm depending on the condition) to avoid acute dissection or rupture (Level of Evidence: C).* Among patients with Marfan syndrome and BAV, the ratio of maximal aortic cross-sectional area in square centimeters to the patient's height in meters with a result of > 10 has been proposed as

TABLE 26.6 Causes of Thoracic Aortic Aneurysm

Etiology	Aortic segment involved	Pathophysiology
Cystic medial degeneration	Ascending aorta, aortic arch	De novo cystic medial degeneration
Marfan syndrome	Ascending aorta and root, aortic arch	Defective fibrillin; secondary cystic medial degeneration
Loeys-Dietz syndrome	Aortic root aneurysms (98%) and arterial tortuosity, especially of the head and neck vessels	Autosomal dominant; defective transforming growth factor receptor type I or II genes
Ehlers-Danlos syndrome, type IV	Ascending aorta, predominantly aortic arch	Defective collagen; secondary cystic medial degeneration
Bicuspid aortic valve	Ascending aorta and root	Inadequate production of fibrillin; cystic medial degeneration
Familial thoracic aortic aneurysm syndrome	Ascending aorta	Autosomal dominant, 3p24.2-25, 5q13-15, 11q23.2-q24
Turner syndrome	Ascending aorta and root	Cystic medial degeneration
Advanced age		Cystic medial degeneration
Atherosclerotic	Descending aorta	Atherosclerotic plaques, weakening vessel walls
Traumatic	Aortic isthmus, proximal descending aorta	Damaged vessel wall, intramural hematoma
Inflammatory	Variable	Takayasu arteritis, giant cell arteritis, HLA-B27–associated spondyloarthropathies, others
Infectious	Aortic root (syphilis), variable (mycotic)	Cystic medial degeneration (syphilis), inflammatory changes (mycotic)
Poststenotic	Ascending (aortic stenosis), descending (coarctation)	Hemodynamic insult
Postsurgical	Aortic valve replacement, status post–aortic anastomosis	Weakening of the anastomotic walls
Chronic aortic dissection	Variable	Weakening of false lumen over time

an indication for surgical intervention, particularly since patients with this finding may be at greater risk for spontaneous dissection.

4. **Diagnostic testing.** Unique advantages and disadvantages of each radiographic technique are described in detail in preceding sections. The specific attributes of each technique when evaluating TAA are reviewed below.
   a. The **chest radiograph** frequently shows widening of the mediastinum, unusual aortic contours, or displacement of the trachea or bronchi in the presence of a large TAA.

b. Both computed tomography angiography (CTA) and MRA provide excellent assessment of size and extent of aneurysmal involvement. CTA is the preferred modality for serial follow-up after surgical or endovascular repair, whereas MRA is the preferred modality when visualization of the aortic root is necessary.

c. TTE and TEE. TTE is of limited use in evaluating the thoracic aorta, except for the aortic root and proximal ascending portion. TEE can be used to visualize the entire thoracic aorta, but given the availability of noninvasive imaging to diagnose TAA, TEE is not routinely used for this purpose.

d. MRI and MRA are also useful for detecting and defining the extent of aneurysmal involvement. They allow for evaluation of the entire aorta, branch vessels, aortic valve, and pericardium.

e. Aortography allows for evaluation of the segment involved by the aneurysm as well as the branch vessels off the aorta. This procedure is currently reserved for preoperative evaluation to establish branch vessel patency.

5. Therapy

a. Medical therapy. Long-term data on medical management for TAA are lacking. Based on one small prospective trial of patients with Marfan syndrome, patients treated with propranolol enjoyed a slower rate of aortic dilatation. *β-Blockers are generally recommended for all patients with TAA, but particularly those with Marfan syndrome to reduce the risk of aortic dilatation (Level of Evidence: B). Antihypertensive therapy should be administered to hypertensive patients with TAA to achieve a goal blood pressure < 140/90 mm Hg, or < 130/80 mm Hg among patients with concurrent diabetes mellitus or chronic kidney disease (Level of Evidence: B). The angiotensin receptor blocker losartan may be particularly beneficial to slow aneurysm growth in patients with Marfan syndrome (class IIa, Level of Evidence: B).* Losartan has been shown in animal models of Marfan syndrome to slow the rate of dilatation of the aorta and human studies are underway.

b. Endovascular therapy. Use of percutaneous aortic stent-grafts has been reported in aortic arch and descending thoracic aneurysms. Contemporary studies, including the Talent VALOR and Zenith TX2 trials, have suggested that endovascular therapy represents a safe and effective strategy and an alternative to open surgery in patients with TAA. However, these studies have also exposed limitations of EVAR including restricted applicability due to a need for careful patient selection with anatomy appropriate for endovascular techniques, vascular access and device implantation issues, and need for concomitant subclavian and less commonly carotid artery bypass grafting, among others. Larger studies and longer follow-up must be presented before widespread use of this technology can be encouraged. Currently, EVAR is reserved for TAA among patients at high risk for open repair among those with ideal aortic anatomy having the procedure performed in centers with a qualified team to perform open aortic surgery.

c. Preoperative evaluation for TAA

(1) *In preparation for surgery, imaging studies adequate to establish the extent of disease and the potential limits of the planned procedure are recommended (Level of Evidence: C).*

(2) *Patients with thoracic aortic disease requiring a surgical or catheter-based intervention who have symptoms of myocardial ischemia should undergo additional studies to determine the presence of significant coronary artery disease (Level of Evidence: C). Patients with unstable coronary syndromes and significant coronary artery disease should undergo preoperative revascularization or concomitant coronary artery bypass graft surgery (Level of Evidence: C).*

d. Surgical therapy for TAA. The technical details of repair are beyond the scope of this text. However, the basic premise is for a Dacron tube graft to be inserted in place of the diseased aorta. The main branches are reimplanted to the graft (coronary arteries, great vessels, mesenteric, and T_8 to L_2 intercostals/lumbricals). When the aortic valve is involved with aortic root dilatation, a modified **Bentall procedure** (composite prosthetic aortic valve with Dacron graft) or **aortic valve homograft** is performed. The aortic valve homograft is a cryopreserved cadaveric aortic valve with a portion of the original ascending aorta intact. Aneurysms involving both the ascending and descending aorta can be treated by a two-staged approach, with an **elephant trunk** procedure. With this, the ascending aorta and arch are replaced initially and the distal portion of the graft is suspended into the proximal portion of the descending thoracic aorta for subsequent union with a descending aorta graft placed either by open surgical procedure or percutaneously. Overall perioperative survival is reported to be 90% to 95% for elective repair (ascending aorta) in most institutions.

(1) *Patients with Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes and other patients with dilatation of the aortic root and sinuses of Valsalva should undergo excision of the sinuses in combination with a modified valve-sparing root reimplantation (David) operation if technically feasible or, if not, root replacement with valved graft conduit (Level of Evidence: B).*

(2) *For patients with degenerative or traumatic aneurysms of the descending thoracic aorta exceeding 5.5 cm, saccular aneurysms, or postoperative pseudoaneurysms, endovascular stent-grafting should be strongly considered if feasible (Level of Evidence: B).*

(3) *For patients with thoracoabdominal aneurysms, in whom endovascular stent-graft options are limited and surgical morbidity is elevated, elective surgery is recommended if the aortic diameter exceeds 6.0 cm, or less if a connective tissue disorder such as Marfan or Loeys-Dietz syndrome is present (Level of Evidence: C).*

(4) *For patients with thoracoabdominal aneurysms and with end-organ ischemia or significant stenosis from atherosclerotic visceral artery disease, an additional revascularization procedure is recommended (Level of Evidence: B).*

e. Complications after TAA repair. These include MI (7.2%), CVA (4.8%), acute renal failure (2.4%), perioperative hemorrhage (7.2%), and paraplegia (6.0%) due to perioperative ischemia of the anterior spinal cord. Procedural adjuncts, including epidural cooling, distal aortic perfusion to support collateral circulation to the spinal cord during surgery, and motor-evoked potential monitoring, have been used to reduce the rate of paraplegia.

(1) Factors associated with increased surgical risk include emergent surgery, greater age, prolonged cross-clamp time, diabetes, previous aortic surgery, and intraoperative hypotension.

IV. CONTROVERSIES AND FUTURE RESEARCH DIRECTIONS

A. Screening for AAA. The U.S. Preventive Services Task Force (USPSTF) currently recommends one-time screening for AAA by ultrasound in men aged 65 to 70 years who have ever smoked, although it makes no recommendation for screening of men that have never smoked. What's more, the USPSTF recommends against routine screening for AAA in women. These recommendations are based on a systematic review of four large randomized trials of screening for AAA, with ultrasound beneficial among ever-smoking men aged 65 to 79 years alone. Further investigation is needed to refine the concept of screening for AAA, particularly in women.

B. Risks and Benefits of Imaging Technologies. Compared with acute coronary syndromes, acute aortic syndromes are less common, although several features of

each disease overlap. When acute aortic disease is suspected, rapid and accurate assessment is required so as to avoid delays in treatment of acute coronary syndromes, as suggested by ECG. What's more, imaging techniques used for aortic disease requiring longitudinal follow-up must be cost-effective and avoid unnecessary radiation exposure. Clinical studies exploring cost-effectiveness and safety of various screening protocols are needed.

C. Clinical Therapeutic Trials for Aortic Syndromes. The National Heart, Lung, and Blood Institute has recommended an Aortic Aneurysm Clinical Trials Network be developed to test medical and surgical treatments among patients with TAA. Significant interest and efforts are underway to develop novel therapeutic targets and biomarkers for acute aortic dissection using animal models. Gene-based models that describe mechanisms of aortic disease based on specific mutations have contributed greatly to our understanding of Marfan, Loeys-Dietz, and other familial syndromes. Further collaborative efforts and expansion of existing registries are likely to improve understanding and provide more effective treatments for diseases of the aorta.

CHAPTER 27

Femi Philip

Peripheral Arterial Disease

I. INTRODUCTION. Peripheral arterial disease (PAD) describes the pathologic states that lead to stenoses and aneurysms in the noncoronary arterial circulation. This chapter focuses on the diseases of the **arterial supply to the extremities** and the **renal vasculature** (disease states involving the aorta and cerebral vasculature are discussed elsewhere in this volume). PAD can be classified as occlusive or aneurysmal. **Atherosclerosis is the most common cause of PAD**. In **aneurysmal** states, weakening of the arterial media results in focal dilatation of the artery to at least 1.5 times the normal diameter. These aneurysmal segments can subsequently dissect, rupture, or thrombose, with catastrophic consequences. In addition to atherosclerosis, there are several less common pathologies that can cause PAD, including vasculitis, arterial injury, entrapment syndromes, and cystic adventitial disease. These disorders are beyond the scope of this chapter.

II. LOWER EXTREMITY PERIPHERAL ARTERY DISEASE

A. Etiology and natural history. Atherosclerosis is the most common cause of lower extremity PAD. Traditional risk factors include age, smoking history, diabetes mellitus, hyperlipidemia, and hypertension. Emerging risk factors include elevated

markers of inflammation such as C-reactive protein, fibrinogen, and interleukin 6; chronic kidney disease; hypercoagulable states such as hyperhomocysteinemia; and possibly a genetic predisposition to PAD. African Americans have a twofold increase in risk of developing PAD. The prevalence of PAD increases significantly with age, such that the prevalence is 2% to 3% in persons aged ≤ 50 years and up to 20% in persons aged > 70 years. **Fibromuscular dysplasia (FMD)**, a noninflammatory and nonatherosclerotic process, can also affect the lower extremities by causing hyperplastic cell growth and luminal narrowing, although it predominantly affects the renal and carotid arteries. Patients with lower extremity PAD may present with leg symptoms or may be entirely asymptomatic. Approximately 50% of patients > 55 years old with PAD, with or without claudication symptoms, when followed for 5 years will remain stable or improve with exercise and lifestyle modifications. The remaining 50% will have progressive worsening of symptoms, and approximately 4% will require major amputation if they do not undergo revascularization. The highest risk of amputation occurs in those patients who are diabetic and continue to smoke. **Cardiac disease accounts for the majority of deaths in patients with PAD, in whom the relative risk of death from cardiac causes is increased more than sixfold. Approximately one-third to one-half of all patients with PAD will have concomitant coronary disease depending on the diagnostic criteria utilized, and thus PAD is considered a coronary artery disease risk equivalent**.

B. Clinical manifestations

1. **Signs and symptoms.** Rest perfusion of the lower extremities may be adequate; however, if the arterial stenosis is severe, then exercise may precipitate ischemia and **claudication**. Symptoms may include pain, discomfort, or fatigue of the buttock, thigh, or calf musculature and are usually gradual in onset. The amount of exercise required to precipitate pain is roughly related to the severity of the stenosis. Pain is usually manifested one segment below the area of severe stenosis (Table 27.1), and the most frequently involved artery in intermittent claudication is the superficial femoral artery. The symptoms are usually promptly relieved with rest or standing. More severe stenosis or more distal atherosclerotic lesions may result in **limb-threatening ischemia with foot pain at rest, tissue ulceration, or gangrene**. There are two terms frequently used to describe this condition that should be differentiated: critical limb ischemia and acute limb ischemia. **Critical limb ischemia** is resting limb pain that results from severe atherosclerotic disease that compromises distal blood flow of the involved limb. This term is typically used to describe chronic lesions such as ischemic rest pain, ischemic ulcers, or gangrene and is caused by a slow progression of atherosclerotic disease. **Acute limb ischemia** occurs abruptly and threatens the viability of the involved tissue. Acute limb ischemia is usually the result of an embolic event or arterial thrombosis.
2. **Physical examination.** Characterization of **femoral, popliteal, dorsalis pedis, and posterior tibial pulses**; **auscultation for bruits** in the abdomen and

TABLE 27.1 Localization of Peripheral Arterial Disease

Foot	Tibial or peroneal arteries

[a]Most commonly involved artery.

bilateral groins; and palpation for **aneurysm** in the abdomen and over the popliteal arteries are all part of a comprehensive lower extremity vascular examination. A complete cardiac examination and auscultation of carotid arteries should also be performed to assess for concurrent abnormalities, given the common atherosclerotic pathogenesis of cerebral, myocardial, and peripheral arterial disease. Signs of lower extremity arterial insufficiency can include coolness, dry skin and scaling, pallor that is worsened with leg elevation, and ulcerations. Rarely muscular atrophy can be seen. The evaluation of a patient with possible acute limb ischemia should include the "5 P's": pain, pallor, pulselessness, paresthesias, and paralysis. These clinical features have prognostic value in acute limb ischemia (Table 27.2).

C. Diagnostic evaluation (Fig. 27.1)

1. **Ankle–brachial index (ABI).** The ABI is a measurement of lower extremity perfusion, which compares the blood pressure in a pedal artery with the higher of two brachial artery blood pressures. The ABI cannot localize stenosis, but is a simple and accurate measure of disease severity (Table 27.3). In general, ABI value correlates poorly with symptoms, and two patients with the same ABI may have remarkably different complaints. **Symptoms at rest rarely occur, unless the ABI is < 0.4 (i.e., critical limb ischemia)**. The ABI has limited use in noncompressible, calcified vessels. In patients with noncompressible ankle vessels (ABI > 1.4) the toe–brachial index can be used in conjunction with pulse-volume recordings (PVRs) to document PAD. Measuring the ABIs before and after exercise can help diagnose PAD when the resting ABI is normal but there is a high clinical suspicion for PAD. It can also help differentiate between true claudication and nonarterial leg pain (pseudoclaudication).
2. **Pulse-volume recordings.** PVRs detect changes in the volume (arterial flow) of the limb during the cardiac cycle. Blood pressure cuffs are placed at the thigh (one or two cuffs), calf, ankle, midfoot, and toe. The change in volume of the respective cuff during the cardiac cycle identifies the presence of arterial stenosis by reduction in the pulsatile flow as detected by changes in pulse contour and amplitude at that cuff, as documented by the PVR waveform (Fig. 27.2). Segmental blood pressure measurements may be taken along the leg with the segmental PVR tracings for localization of disease. Unlike ABIs, arterial

TABLE 27.2 Categorizing Acute Limb Ischemia

Category	Prognosis	Sensory loss	Muscle weakness	Arterial Doppler signal	Venous Doppler signal
Viable	Not immediately threatened	None	None	Audible	Audible
Threatened marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Often inaudible	Audible
Threatened immediately	Salvageable with immediate revascularization	More than toes, rest pain	Mild, moderate	Usually inaudible	Audible
Irreversible	Major tissue loss or permanent nerve damage	Profound anesthesia	Profound paralysis	Inaudible	Inaudible

calcification does not effect PVR tracings, and PVR can often be helpful in the diabetic patient with a foot ulcer and suspected arterial calcification.

3. **Duplex ultrasound.** Arterial duplex renders an anatomic assessment of the arterial system using a combination of B-mode ultrasound imaging and Doppler frequency spectral analysis. Doppler complements the standard qualitative ultrasound imaging by allowing waveform analysis and assessment of Doppler velocities. Using the concept that velocity of blood flow increases as it flows through a stenotic lesion, peak systolic and end-diastolic velocities are measured and used to estimate the severity of a stenosis. This modality is useful for anatomic visualization of lesions and for surveillance after stenting or bypass grafting.

TABLE 27.3 Evaluating Disease Severity with the Ankle–Brachial Index

ABI	Interpretation
1.3	Noncompressible vessel
1.0–1.29	Normal
0.91–0.99	Equivocal
0.4–0.90	Mild to moderate PAD
< 0.4	Severe PAD

ABI, ankle–brachial index.

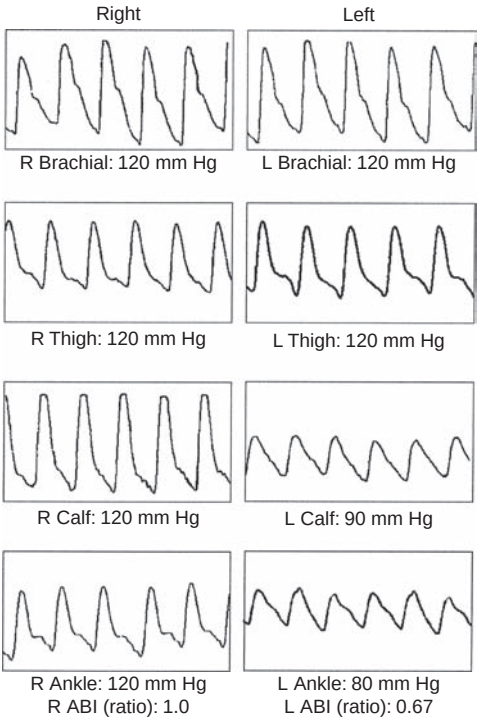

FIGURE 27.2 Pulse-volume recording (PVR) of the lower extremities. This PVR was obtained from a 42-year-old man with a history of diabetes mellitus and tobacco use who developed new left calf cramping with exertion. It demonstrates moderate disease (ankle–brachial index [ABI] = 0.66) of left femoropopliteal segment and a normal recording on the right lower extremity. He was advised to begin both a tobacco cessation program and a walking regimen.

4. **Magnetic resonance angiography (MRA).** The MRA signal is a reflection of the velocity and flow patterns of protons within the artery. The noninvasive nature of MRA and its ability to generate three-dimensional (3D) reconstructions are the main advantages of MRA over conventional angiography. Its limitations include a tendency to overestimate lesion severity secondary to flow turbulence, imaging artifact with metal clips or stents, and its association with nephrogenic systemic fibrosis (2.5% to 5.0%) in patients with a glomerular filtration rate < 30 mL/min. Despite these limitations, MRA still has a class I indication to diagnose the anatomic location and severity of stenosis in patients with PAD.
5. **Computed tomographic angiography (CTA).** CTA is a rapidly progressing technology that uses an intravenous contrast agent and a multidetector scanner to obtain images that are of similar quality to those of conventional angiography. A total of 64 detector scanners allow the simultaneous acquisition of 64 cross-sectional image slices; this has dramatically reduced radiation and contrast doses required to obtain adequate images. CTA has the advantage of being capable of reconstructing 3D images in virtually any oblique projection to help evaluate

eccentric stenoses. Other advantages of CTA include better visualization of collaterals to distal vessels, identification of aneurysms, and cystic adventitial disease, which may not be picked up by conventional angiography. CTA also has several disadvantages when compared with catheter-based angiography: CTA has lower spatial resolution than digital subtraction, venous opacification can interfere with visualization of arterial filling, asymmetric leg filling may miss the arterial phase in some vessels, and the enormous quantity of data obtained (up to 2,000 images) may be difficult for workstations to process and store. Several recent studies have shown the accuracy of CTA for the diagnosis of stenoses > 50%, and CTA is quickly becoming an important imaging modality for the diagnosis of PAD. Currently, the American College of Cardiology/American Heart Association (ACC/AHA) PAD guidelines give a class IIb indication for CTA in the diagnosis of the anatomic location and severity of stenosis in patients with PAD.

6. **Catheter-based angiography.** Long considered the gold standard for the diagnosis of arterial disease, this invasive procedure requires intraarterial vascular access and contrast (often nonionic dye, although gadolinium or carbon dioxide can be used). It is recommended for the evaluation of patients for whom revascularization procedures are planned (those with lifestyle-limiting claudication, rest pain, ischemic ulceration, or gangrene) or for whom noninvasive techniques are inconclusive. Because contrast angiography demonstrates only the arterial lumen, it can underestimate lesion severity. Contrast angiography (Ia) with digital subtraction (Ib) has a class I indication for patients with PAD when revascularization is considered.

D. Treatment. The two main goals of therapy for patients with PAD are to relieve symptoms and improve survival from related cardiovascular diseases. Options for treatment of intermittent claudication include surgical revascularization ("bypass"), percutaneous revascularization, pharmacotherapy, and exercise. Aggressive risk factor modification is the primary therapy for the prevention of cardiovascular events. Therefore, the mainstay of treatment for many patients with mild to moderate claudication is to **"stop smoking and start walking."** Accordingly, a trial of supervised exercise therapy is given a class I recommendation as the initial therapy of choice for claudication in the ACC/AHA PAD guidelines. Supervised exercise therapy ("PAD rehab") has been reported to increase walking distance by up to 130% to 180% among patients with claudication.

1. **Antiplatelet therapy**

Aspirin/clopidogrel. Current guidelines recommend that all PAD patients should be on aspirin (75 to 325 mg) therapy unless contraindicated (class I). Clopidogrel can be used in the setting of aspirin allergy (class I). In a subset analysis of the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial, clopidogrel reduced composite major adverse events by 23.8% compared with aspirin in a large cohort of 19,185 patients with atherosclerotic vascular disease, of whom 6,452 had symptomatic PAD. In terms of dual antiplatelet therapy, the Clopidogrel and Aspirin versus Aspirin Alone for the Prevention of Atherothrombotic Events (CHARISMA) trial failed to show a significant additive reduction in composite cardiovascular events with dual antiplatelet therapy in patients with asymptomatic cardiovascular disease or multiple cardiovascular disease risk factors but did show a reduction in myocardial infarction and hospitalization in a subset of PAD patients, albeit at the cost of higher rates of bleeding.

Since the publication of the guidelines, several recent trials have triggered some debate about the efficacy of aspirin for prevention of cardiovascular events in patient with PAD. The Prevention of Progression of Arterial Disease and Diabetes (POPADAD) trial comprising 1,276 patients with diabetes and ABI ≤ 0.99 showed that aspirin failed to prevent the composite cardiovascular end point when compared with placebo (hazard ratio [HR] 0.98; 95% confidence interval [CI] 0.76 to

1.26). The Aspirin for Asymptomatic Atherosclerosis (AAA) trial comprising 3,350 patients with ABI ≤ 0.95 and no known cardiovascular disease also showed a failure of aspirin to decrease rates of composite cardiovascular events when compared with placebo (HR 1.03; 95% CI 0.84 to 1.27). A meta-analysis of randomized controlled trials including 18 trials and 5,269 patients showed that while there is a trend for aspirin to prevent cardiovascular events, the difference is not statistically significant (risk ratio [RR] 0.88; 95% CI 0.76 to 1.04). In light of these recent trial data, recommendations from updated PAD guidelines are eagerly anticipated.

2. **Risk factor modification.** PAD is a coronary risk equivalent and as such aggressive risk factor modification is warranted.
   a. Cigarette **smoking** has been associated with progression of atherosclerosis. Physician counseling is essential, as **tobacco cessation can reduce the 5-year amputation risk and decrease the 5-year mortality rate by 50%**. The importance of this intervention cannot be underestimated. Whenever possible, extensive counseling and referral to formal smoking cessation programs should be offered (class I). In addition, several pharmacologic therapies are available (bupropion, nicotine replacement, and varenicline) and should be prescribed when indicated.
   b. Current guidelines recommend treatment of **hypertension** to goal blood pressure < 140/90 mm Hg in patients with PAD and < 130/80 mm Hg in patients with PAD and diabetes or chronic kidney disease to prevent the development of future cardiovascular adverse events. The use of β-blockers as antihypertensive agents in patients with PAD is *not* contraindicated. Given the findings of the Heart Outcomes Prevention Evaluation Study, which included patients with PAD, it is reasonable to treat patients with symptomatic PAD, irrespective of diabetes, with an angiotensin-converting enzyme (ACE) inhibitor to reduce cardiovascular events (class IIa).
   c. Aggressive treatment of **hyperlipidemia** should include therapy with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) whenever possible to achieve a low-density lipoprotein (LDL) goal of < 100 mg/dL in patients with PAD (class I). For patients at especially high risk for ischemic events, an LDL goal of < 70 mg/dL may be desirable (class IIa). Patients with normal LDL cholesterol, low high-density lipoprotein (HDL) cholesterol, and elevated triglycerides may derive benefit from a fibric acid derivative (class IIa).
   d. The management of **diabetes** in patients with PAD is important, given their increased risk of amputation (overall 20%) and increased mortality (estimated to be 50% at 5 years). Current recommendations advocate daily assessment of the feet to aid in the early identification of complications of ischemia, such as foot ulcers (class I). The recommended target HbA1c is < 7.0% (class IIa). Aggressive risk factor modification is a critical component of management for diabetic patients with PAD, and these patients should be treated with antiplatelet therapy, lipid-lowering agents, and ACE inhibitors in the absence of contraindication.
3. **Treatment of claudication**
   a. **Exercise is an inexpensive, low-risk option in comparison with invasive therapies and pharmacotherapies for intermittent claudication.** Potential mechanisms by which exercise improves symptoms include augmentation of collateral flow, improved rheologic characteristics of blood, decreased reliance on anaerobic metabolism, and greater extraction of oxygen. Supervised exercise programs have been shown to improve pain-free walking distance up to 180% from resting values. For patients with symptomatic claudication, current guidelines recommend a supervised exercise program for 30 to 45 minutes three times a week for at least 12 weeks (class I). For patients who do not have a supervised exercise program available to them, a self-directed structured walking program should be encouraged.

b. **Cilostazol** is a type 3 phosphodiesterase inhibitor that suppresses platelet aggregation and acts as a direct arterial vasodilator. Cilostazol also beneficially increases HDL, decreases triglycerides, and inhibits vascular cell adhesion molecule-1 expression, thereby decreasing vascular smooth cell proliferation. Randomized controlled trials of patients with moderate to severe claudication have demonstrated 40% to 60% increases in maximal walking distances with 12 to 24 weeks of therapy with cilostazol 100 mg twice daily. A trial of cilostazol, 100 mg twice daily, is recommended in all patients with PAD and intermittent claudication to relieve symptoms and improve walking distance (class I). Cilostazol is contraindicated in patients with congestive heart failure, owing to an increased risk of sudden death associated with related phosphodiesterase inhibitors. Common side effects associated with cilostazol include diarrhea, palpitations, and headaches.

c. **Pentoxifylline.** Oral pentoxifylline, 400 mg three times daily, can be considered as a second-line alternative to cilostazol in patients with symptomatic claudication (class IIb). Pentoxifylline is a methylxanthine derivative that functions as a vasodilator and an antiplatelet agent, reduces blood viscosity, and improves deformability of erythrocytes and leukocytes to exert its effects. Trials have been divergent on the efficacy of pentoxifylline and is felt to result in only marginal improvements in maximal walking distance and symptoms.

4. **Revascularization.** Revascularization is indicated for "lifestyle-limiting" claudication (after failed medical therapy), rest pain, ischemic ulceration, or gangrene. It may be **performed surgically or percutaneously**.

a. **Percutaneous therapy.** In carefully selected patients, catheter-based revascularization is an attractive alternative to conventional surgical management. Percutaneous revascularization has a class I indication for individuals with lifestyle-limiting claudication when there is a reasonable likelihood of procedural success and there has been an inadequate response to conservative therapy. Percutaneous revascularization is recommended according to the TransAtlantic Inter-Society Consensus II (TASC II) guidelines, which divide lesion anatomy according to location, distribution, length, and likelihood of procedural success. TASC type A lesions are those in which endovascular therapy is recommended, and type B lesions are those in which endovascular therapy is preferred in most cases. For instance, TASC type A disease in the aortoiliac system is defined as unilateral or bilateral disease in the common iliac or external iliac arteries of short length (< 3 cm). In the femoral popliteal region, a type A lesion is defined as a single stenosis ≤ 10 cm in length or a single occlusion ≤ 5 cm in length. Translesional pressure gradients (criteria: threshold peak systolic difference 5 to 10 mm Hg prevasodilation and 10 to 15 mm Hg postvasodilation) should be obtained for angiographic lesions that appear moderately stenotic (e.g., 50% to 75%) prior to intervention (class I). The treatment of choice for focal aortoiliac disease is angioplasty with or without stenting. This approach has a technical success rate of 90%, 2 year patency rate of 73% to 84%, a complication rate of < 10% (usually related to the arterial access site), and periprocedural mortality rate of < 1%. For femoropopliteal disease, patency rates with percutaneous therapies are lower than those in iliac disease; therefore, angioplasty is utilized to manage focal disease after failure of medical therapy. Direct stenting as a primary therapy is not recommended for femoral, popliteal, or tibial arteries; however, stenting may be effective as salvage therapy after suboptimal or failed balloon angioplasty (class I).

b. **Surgical.** Similarly, surgical revascularization also has a class I indication for individuals with lifestyle-limiting claudication when there is a reasonable likelihood of procedural success and there has been an inadequate response to conservative therapy. Surgery is used to bypass long segments of diffuse disease

(particularly involving the femoropopliteal segment) or when endovascular therapy fails. Various conduits, such as reversed or in situ saphenous vein grafts, Dacron grafts, and polytetrafluoroethylene grafts, can be used. For severe disease below the popliteal artery, both percutaneous and surgical revascularization approaches have marginal outcomes with regard to limb salvage. In patients younger than 50 years, the efficacy of surgical intervention for symptomatic claudication is not well established due to the aggressive nature of their atherosclerosis and limited graft durability (class IIb). Given the coincidence of coronary artery disease in these patients, a thorough preoperative assessment of cardiac risk should be performed prior to vascular surgery.

III. LOWER EXTREMITY ANEURYSMS. Aneurysms of the peripheral arteries, as in the aorta, are most commonly due to atherosclerotic disruption of the arterial media. Up to 70% of lower extremity aneurysms involve the popliteal arteries. The incidence of bilateral involvement in lower extremity aneurysm is high (45% to 68%). The majority of patients (62%) with popliteal aneurysms have been reported to have concomitant abdominal aortic aneurysms (AAAs), and this coprevalence increases to 85% in patients with femoral artery aneurysms. Accordingly, patients diagnosed with peripheral arterial aneurysms, especially femoral or popliteal, should be screened with ultrasound for AAA and for the presence of contralateral lower extremity disease (class I). The greatest concern with lower extremity aneurysms is thrombosis and thromboembolism. Lower extremity aneurysms infrequently rupture (7% to 12%), but up to 60% will have an ischemic complication; therefore, acute limb ischemia is the most common presenting symptom. As an aneurysm increases in size, it can compress adjacent venous and lymphatic structures causing lower extremity edema. Given the risk of thrombosis, it is recommended that popliteal aneurysms > 2.0 cm (class I) and femoral artery aneurysms > 3.0 cm be repaired. Unless symptomatic, aneurysms of smaller caliber should be followed by annual arterial duplex ultrasound examinations (class IIa).

IV. UPPER EXTREMITY ARTERIAL DISEASE. In addition to atherosclerosis, the most common cause of upper extremity PAD, other pathologic states can result in stenosis of the upper extremity arteries. These disorders include vasculitis (particularly Takayasu and giant cell arteritis), FMD, thoracic outlet syndrome, ionizing radiation, and repetitive injury. Associated clinical symptoms include arm and hand claudication, digital ulceration, and neurologic symptoms caused by vertebral–subclavian steal. The diagnostic modalities are similar to those in lower extremity arterial disease. The simple clinical maneuver of checking blood pressure measurements in both arms is an excellent screening test for significant upper extremity PAD. Risk factor modification and revascularization (for symptomatic patients) are the mainstays of therapy. Finally, a high index of suspicion for concurrent cardiovascular and cerebrovascular disease should be maintained.

V. RENAL ARTERY DISEASE

A. Clinical manifestations. Renal artery stenosis (RAS) is commonly associated with two clinical syndromes: hypertension and ischemic nephropathy. Clues to the presence of RAS include the following: **abrupt onset of hypertension** (before age 30 years, often due to FMD, or after age 55 years, often due to atherosclerotic disease); **previously well-controlled essential hypertension that becomes resistant to medical therapy** (three-drug regimen including a diuretic); **azotemia**, which is unexplained or induced by ACE inhibitor administration; and **recurrent flash pulmonary edema**, often with normal left ventricular function (due to renin-angiotensin–mediated volume overload and peripheral vasoconstriction). Physical examination in RAS may reveal hypertension, epigastric bruits, and evidence of atherosclerosis in other vascular beds (e.g., carotid or femoral bruits and diminished pedal pulses). Renal imaging can reveal an atrophic kidney or a size discrepancy between the two kidneys.

B. Etiology and natural history. The most common causes of RAS are atherosclerosis and FMD. Atherosclerosis accounts for 90% of RAS and usually involves the ostium and proximal third of the main renal artery. The prevalence of atherosclerotic RAS increases with age, particularly in patients with diabetes, aortoiliac disease, coronary artery disease, or hypertension. Studies have suggested that the prevalence of RAS in patients with PAD may be as high as 59%. It is the most common cause of secondary hypertension, may account for 1% to 5% of all cases of hypertension, and may be the cause of end-stage renal failure in up to 20% of new dialysis patients. RAS is an independent risk factor of mortality in patients with other vascular diseases. Moreover, end-stage renal disease due to RAS is associated with the highest mortality (median survival of 2.7 years) among all dialysis-dependent patients. FMD accounts for < 10% of cases of RAS, but should be suspected in younger patients without atherosclerotic risk factors who present with RAS. It more frequently affects the distal two-thirds of the main renal artery and its branches, and in the most common type of FMD, medial fibroplasia, there is a characteristic "string of beads" appearance on angiography. The cause of FMD is unknown. Rarer causes of RAS include vasculitis, neurofibromatosis, congenital bands, extrinsic compression, and ionizing radiation.

C. Diagnostic evaluation

1. **Laboratory studies.** Blood urea nitrogen and serum creatinine are readily available and are often used in practice as screening tools. Although azotemia and increased serum creatinine are neither sensitive nor specific for RAS, they may be the first clue to the disease. Urinalysis in RAS usually reveals proteinuria and a bland sediment. Because of the advent of sensitive and specific noninvasive imaging modalities, plasma renin activity and selective renal vein renin measurements are not recommended as screening tests to diagnose RAS (class III).
2. **Duplex ultrasonography (DUS).** Arterial duplex uses a combination of B-mode ultrasound imaging and Doppler frequency spectral analysis. Elevated peak systolic velocities, the renal-to-aortic ratio, and the presence of color and spectral turbulence are criteria used to determine the presence of significant RAS. In addition, DUS allows for calculation of the renal resistive index (renal parenchymal peak systolic velocity minus end-diastolic velocity divided by the peak systolic velocity), which is a potential marker of renal parenchymal disease. Some data suggest that patients with an elevated resistive index may not improve after revascularization. DUS is inexpensive, widely available, and highly sensitive and specific for RAS when compared with angiography (reported sensitivities between 84% and 98% and reported specificities between 62% and 99%). It is also highly useful for surveillance of renal arteries after stenting, as flow through a stent can be easily detected, in contrast to MRA, which is limited by metal artifact. DUS for RAS must be performed in experienced centers. The test may be limited by difficulty in obtaining measurements due to excess bowel gas or obesity. It also has lower sensitivity (64%) for identifying accessory renal arteries, narrowing of which could also lead to the signs of RAS.
3. **Renal scintigraphy.** Radionuclide renal imaging is used to assess differential renal blood flow and has been used in conjunction with captopril renography to attempt to diagnose RAS. Captopril renography precipitates an ACE inhibitor–mediated fall in glomerular filtration to amplify differences in renal perfusion consistent with RAS. Due to a relative lack of sensitivity (74%) and specificity (59%) compared with catheter-based angiography, captopril renography is no longer recommended for the screening of RAS (class III).
4. **Magnetic resonance angiography.** MRA now has a class I indication as a test for the diagnosis of RAS, with reported sensitivity and specificity from 90% to 100% and 76% to 94%, respectively, when compared with angiography. MRA is noninvasive and has the ability to generate 3D reconstructions. Its limitations include expense, limited availability, lack of resolution in the setting of high-grade

stenosis (often appearing as an occlusion or loss of signal), a tendency to overestimate lesion severity, and difficulty with post–stent imaging due to artifact. It is also less sensitive for the detection of FMD, given that the typical arterial beading may be subtle and resolution of MRA is still limited, particularly of the distal renal vasculature. In addition, in patients with advanced renal insufficiency or renal failure, gadolinium-containing contrast agents have been linked to nephrogenic systemic fibrosis in 2% to 3% of patients (see Chapter 51). This has complicated the use of contrast-enhanced MRI in patients with RAS and renal insufficiency.

5. **Computed tomographic angiography.** Like MRA, CTA has the capability of producing excellent 3D images of the renal arteries as well as the aorta and other visceral vessels. CTA has a sensitivity and specificity for detecting significant RAS ranging from 59% to 96% and 82% to 99%, respectively. Contrast administration (100 to 150 mL) and radiation dose remain limitations of CTA. Unlike MRA, CTA does not have significant imaging artifact with metal clips or stents and, therefore, can be used to detect in-stent restenosis.
6. **Renal arteriography.** This is the gold standard for the diagnosis of RAS. It allows for excellent visualization of the main renal and accessory renal arteries and their branches. Arteriography allows for assessment of the degree of stenosis visually and adds the ability to obtain hemodynamic measurements (gradients) across the stenotic lesions. Disadvantages include the requirement for intraarterial access and nephrotoxic radiocontrast.

D. Treatment. Despite antihypertensive therapy, RAS tends to progress and may be associated with renal ischemia and loss of renal function (i.e., renal insufficiency). Atherosclerotic nephropathy is complex and not simply related to stenosis of the renal artery. Examination of renal histology in patients with atherosclerotic nephropathy reveals other potential mechanisms for loss of function, including small-vessel occlusion from atheroemboli, intrarenal arterial stenoses, and preexisting hypertensive nephrosclerosis. Importantly, as with other peripheral vascular disease processes, a high index of suspicion for concurrent cardiovascular and cerebrovascular disease should be maintained.

1. **Medical therapy.** Aggressive antihypertensive therapy using multiple agents remains the mainstay of RAS therapy and is often the control arm of randomized trials of interventional approaches to RAS. ACE inhibitors, angiotensin receptor blockers, diuretics, β-blockers, calcium channel blockers, and various other antihypertensives have been shown to be effective in treating hypertension associated with RAS. ACE inhibitors and angiotensin receptor blockers should not be used in patients with bilateral RAS or a solitary kidney with RAS. However, these agents can be highly effective in the management of hypertension in patients with unilateral RAS (class I). Patients with RAS should be treated to achieve blood pressure targets consistent with the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of Hypertension. Aggressive atherosclerotic disease risk factor modification should be part of a comprehensive treatment plan.
2. **Percutaneous revascularization.** The principle behind revascularization is that early restoration of renal artery patency in patients with atherosclerotic RAS may improve hypertension management and minimize progressive renal dysfunction; however, there is a paucity of data from controlled clinical trials to show that revascularization for RAS improves hypertension or delays renal dysfunction. Two small randomized trials demonstrated that patients treated with percutaneous renal artery angioplasty had improved systolic blood pressure and/or blood pressure control (as measured by a reduction in the number or dose of antihypertensive agents used) compared with patients treated with antihypertensive therapy alone. Response to percutaneous intervention is better among patients with FMD than those with atherosclerotic RAS, a finding that may be expected given the pathology that is seen at multiple levels in renal vasculature with atherosclerotic RAS. Congestive

heart failure and chronic obstructive pulmonary disease have been shown to be independent predictors of increased mortality in patients undergoing renal artery stenting; however, baseline azotemia remains the strongest predictor of long-term mortality (70% 5-year mortality rate with serum creatinine > 2.5 mg/dL).

Revascularization for RAS has been shown to stabilize or improve renal function in patients with symptomatic RAS up to 1 year after intervention. In the ACC/AHA PAD guidelines, the only class I indication for percutaneous renal artery revascularization is hemodynamically significant RAS in patients with recurrent unexplained pulmonary edema or congestive heart failure. Other clinical scenarios in which percutaneous renal artery revascularization for hemodynamically significant RAS can be considered (class IIa) are uncontrolled/malignant hypertension, progressive chronic kidney disease with bilateral RAS, RAS in a solitary functioning kidney, or unstable angina with RAS. A hemodynamically significant lesion in RAS is defined as any lesion with > 70% stenosis or a lesion that has 50% to 70% stenosis with a translesional pressure gradient > 20 mm Hg or mean gradient > 10 mm Hg. In terms of revascularization technique, renal artery stent placement has a class I indication for ostial atherosclerotic RAS. Stenting is also recommended as bailout therapy following failed angioplasty in renal FMD, although angioplasty alone is generally successful in this disorder. Predictors of poor outcomes with RAS interventions include significant proteinuria (> 1 g/d), renal atrophy, parenchymal renal disease, and diffuse renal arterial disease.

3. **Surgical revascularization.** Vascular surgery approaches to RAS include surgical bypass (aortorenal, celiac-renal, or mesenteric-renal) and endarterectomy. Perioperative mortality rates range from 1% to 5%. The comparable procedural success with percutaneous approaches and fewer major complications have led to a decline in the number of vascular surgeries for RAS. In the setting of RAS and aortic disease (either aneurysmal or occlusive), surgical revascularization with renal artery bypass grafting is the preferred approach (class I). Surgical revascularization is also recommended for patients with significant atherosclerotic RAS and clinical indications for intervention with multiple renal arteries or early branching main renal artery (class I). In patients with FMD, surgical revascularization is recommended for RAS associated with macroaneurysms or complex disease involving segmental renal arteries (class I).
4. **Controversies.** Among existing revascularization procedures for peripheral vascular disorders, renal artery stenting is possibly the most widely applied and poorly tested. To date, there are no published randomized controlled trials demonstrating the superiority of renal artery stenting over optimal medical therapy (risk factor modification, aggressive antihypertensive therapy, lipid reduction therapy, and aspirin) for RAS. In addition, the ability of renal artery stenting to decrease mortality or progression to dialysis or to provide prolonged benefits in blood pressure control remains uncertain. The National Institutes of Health (NIH)–sponsored Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) trial is the first large randomized controlled trial comparing medical therapy with medical therapy plus renal artery stenting for the treatment of patients with systolic hypertension and RAS, and its findings are awaited with interest.

CHAPTER 28

Hemal Gada

Carotid Artery Disease

I. EPIDEMIOLOGY AND ETIOLOGY OF STROKE

A. Annually, there are nearly 800,000 strokes in the United States and 15 million strokes worldwide. Stroke is the **third leading cause of death** in Western societies and the leading cause of long-term disability in the United States.

B. Ischemic stroke accounts for approximately 85% of all strokes and can be classified into two broad categories.

1. **Embolic:** May be arterial (e.g., aortic atheroma or large vessel atherosclerosis in the carotid, vertebral, or basilar arteries) or cardiac (e.g., left ventricular thrombus postmyocardial infarction [post-MI], atrial fibrillation, valvular disorders, and cardiac tumors) in origin and most often occurs suddenly, with deficits indicating focal loss of brain function.
2. **Thrombotic:** May be caused by stenosis of smaller intracerebral arteries, a hypercoagulable state, or a systemic inflammatory condition causing vasculitis, with symptoms that may fluctuate in presence and intensity.

II. NORMAL CAROTID ANATOMY

A. The aortic arch normally gives rise to the innominate artery (aka brachiocephalic artery), the left common carotid artery (CCA), and the left subclavian artery (Fig. 28.1). The innominate artery bifurcates into the right CCA and the right subclavian artery. The **left common carotid arises from the aortic arch in 70% of people and from the innominate artery in 20% ("bovine arch" variant)**.

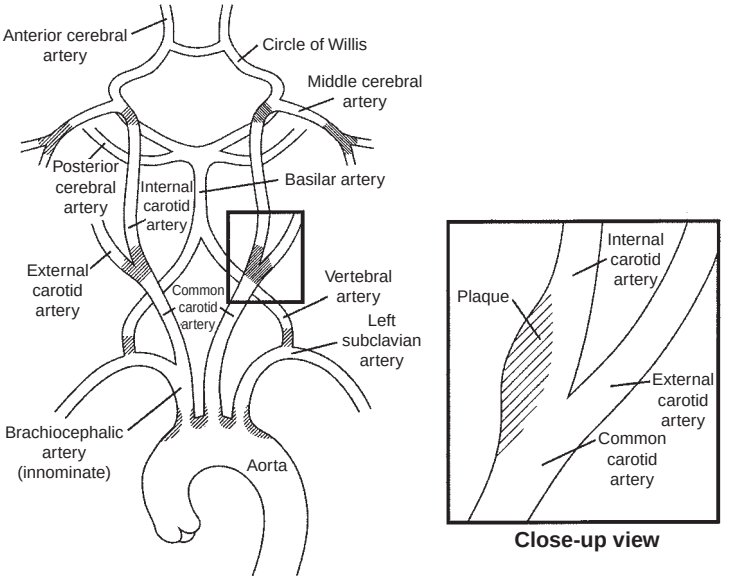

FIGURE 28.1 Normal anatomy of the aortic arch, great vessels, and circle of Willis. The *shaded regions* depict the areas most prone for the development of atherosclerosis.

B. The aortic arch can be classified into three types based on the distance of the origin of the great vessels from the top of the arch (Fig. 28.2). The widest diameter of the left common carotid is used as a reference unit. If all the great vessels originate **within an arc of the aortic arch subtended by a line parallel to a horizontal reference line at the top of the arch and separated from the top reference line by the reference unit**, it is classified as a **type I arch**. In a **type II arch**, all the great vessels originate within an arc **within two reference units** from the top of the arch, and in a **type III** arch the great vessels **originate within an arc beyond two reference units** from the top of the arch. Type III arches are harder to access during percutaneous intervention than type I arches.

C. The CCAs divide into the internal and external carotids at the C4-5 level in 50% of the patients. In approximately 40% of patients, the bifurcation is higher, and it is lower in the remaining 10%.

D. The external carotid artery provides flow to the facial muscles, scalp, and thyroid. It has a complex system of collaterals, and symptoms from stenosis are rare.

E. The circle of Willis provides collateral flow between the left and right hemispheres of the brain and connects the anterior and posterior circulation.

III. RISK FACTORS FOR CAROTID ATHEROSCLEROSIS

A. **Smoking and age** are the two most important risk factors for developing carotid atherosclerosis. The others, in order of importance, are **hypertension, diabetes, gender (men more than women if younger than 75 years; women more than men if older than 75 years), and hyperlipidemia**. As with coronary artery disease (CAD), inflammation likely plays a major role in carotid disease. African American men and Hispanic Americans appear to have a higher incidence of carotid atherosclerosis. Some data suggest a role for chronic infection in the development of carotid disease.

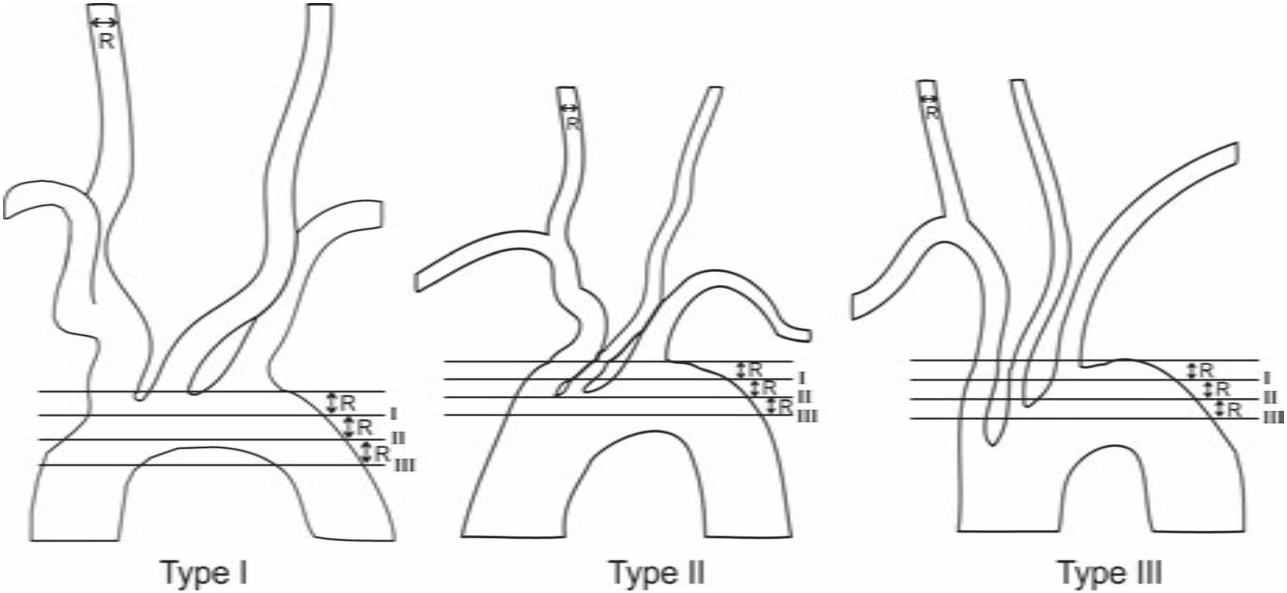

FIGURE 28.2 Aortic arch classification. The classification system is based on the distance of the origin of the great vessels from the top of the arch.

B. Elevated serum lipoprotein(a) has been associated with intracranial, extracranial, and aortic large artery occlusive disease.

C. Between 30% and 60% of patients with peripheral arterial disease have carotid disease, and approximately 50% to 60% of patients with carotid disease have severe CAD. However, only 10% of patients with CAD have severe carotid disease.

IV. PATHOPHYSIOLOGY

A. As with coronary disease, atherosclerotic carotid disease usually develops at branch points and bends, especially at the bifurcation of the CCA and origin of the internal carotid artery (ICA) (Fig. 28.1).

B. Plaque is most often localized at the carotid bifurcation and tends to extend from the outer wall of the carotid bulb into the ICA origin (Fig. 28.1).

C. The reasons that carotid stenoses become symptomatic are not completely understood, but there is a linear increase in the risk of stroke as the stenosis increases to > 70%. Two hypotheses explain how carotid disease can cause stroke.

1. **Carotid plaque is highly vascularized.** Rupture of this vasculature or rupture of the plaque can result in plaque hemorrhage or ulceration, with subsequent in situ thrombus formation. This can lead to complete vessel obstruction or distal atherothromboembolism. This mechanism accounts for most cerebrovascular events caused by carotid disease.
2. Larger plaques can result in high-grade carotid stenosis or obstruction, with subsequent ischemic stroke due to a reduction in cerebral flow, in the setting of inadequate or absent collateral circulation.

V. DIAGNOSIS

A. History and physical examination

1. **Careful history can aid in the localization of neurologic symptoms. Hemispheric symptoms include unilateral weakness, numbness, difficulty with speech, and visual field defects, whereas vertebrobasilar symptoms can include cerebellar disturbances such as ataxia or brain stem symptoms including syncope, dysphagia, dysarthria, or diplopia. Amaurosis fugax is transient, unilateral vision loss ipsilateral to a carotid lesion.**
2. **An assessment for the presence of a cervical bruit is an important part of the physical examination but should not be relied on as the sole marker for the presence of carotid disease.** In the North American Symptomatic Carotid Endarterectomy Trial (NASCET), the presence of a cervical bruit had an approximately 60% sensitivity and specificity for high-grade carotid stenosis. In the Framingham study, the presence of a carotid bruit in asymptomatic patients doubled the risk of stroke, but most of these strokes occurred in vascular beds different from those of the carotid bruit. The presence of a bruit may be a general marker for patients at higher risk for cerebrovascular and cardiovascular events.
3. **In addition to auscultation for carotid bruits, a complete evaluation in a patient with symptoms includes a focused neurologic examination to correlate symptoms with neurologic territory, a funduscopic examination to detect retinal embolization, and a cardiac examination to rule out potential cardioembolic sources for symptoms.**
4. All patients should have an evaluation of the carotid arteries after a stroke or a transient ischemic attack (TIA). The risk of a second stroke is elevated for several years after the first stroke or TIA. Symptomatic patients with 70% or more stenosis have an 8% risk of stroke at 30 days and a 13% annual incidence of stroke. The risk of stroke in asymptomatic patients increases as the degree of carotid stenosis increases. Asymptomatic patients with 60% or more stenosis have a stroke risk of approximately 2% per year. Asymptomatic patients with 80% or more stenosis have a risk of approximately 5% per year.

B. Duplex ultrasound

1. Although carotid angiography is the gold standard, duplex ultrasound is the most widely used method for the detection and quantification of carotid artery disease. It has a sensitivity and specificity of > 80% among patients with 70% to 99% stenoses and sensitivity and specificity of > 95% among patients with complete carotid occlusion. Due to its high sensitivity and specificity in severe carotid disease and its noninvasive nature, duplex ultrasound should be the first study performed to assess for carotid disease.
2. The ultrasound diagnosis of carotid stenosis is based largely on peak systolic and end-diastolic velocities in the ICA. Duplex ultrasound criteria for carotid stenosis vary by institution, and each vascular laboratory must assess the accuracy of its criteria for stenosis in a quality assurance program. Compared with angiography, duplex ultrasound is noninvasive, less expensive, and can be done at the bedside. Limitations include the inability to image intracranial disease, limited ability to assess collateral flow, occasional inaccuracy in distinguishing high-grade stenoses ("string sign") from complete obstructions, and the need for an experienced sonographer. Conditions that may elevate intravascular flow velocities, such as common carotid disease, vessel tortuosity, contralateral carotid disease, or presence of a carotid stent, may result in an artificially high estimate of ICA stenosis. The ability of ultrasound to assess the posterior carotid circulation is limited.

C. Computed tomography angiography (CTA)

1. CTA offers high sensitivity and specificity for the identification of severe (> 70%) carotid artery disease (sensitivity 75% to 100%, specificity 63% to 95%, negative predictive value up to 100%). CTA allows for visualization of the carotid artery lumen as well as adjacent bony and soft tissue structures. Advantages include high sensitivity (particularly for carotid artery occlusion), reproducibility, and the ability to visualize the entire carotid artery including the extracranial and intracranial portions. Disadvantages include cost and the need for contrast injection, which may be unsuitable for patients with chronic kidney disease or volume overload.

D. Magnetic resonance angiography

1. Contrast-enhanced magnetic resonance angiography (CEMRA) is rapidly gaining acceptance as a sensitive (91% to 95%) and specific (88% to 92%) test for severe carotid disease. Advantages include high sensitivity, reproducibility, and the ability to visualize the entire carotid artery including the extracranial and intracranial portions. The use of a paramagnetic agent as a vascular contrast confers higher quality images less prone to artifact. Disadvantages include high cost and the inability to study critically ill patients, claustrophobic patients, or patients with ferromagnetic implants such as pacemakers.
2. The combination of CEMRA and Doppler ultrasound results in a lower number of misclassifications and higher sensitivity and specificity for the diagnosis of severe ICA stenosis. When there is concern regarding the accuracy of one study, it is justifiable to perform both.

E. Contrast angiography

1. Contrast angiography with digital subtraction angiography (DSA) is the gold standard for assessment of carotid atherosclerosis. It allows the simultaneous assessment of the aortic arch, subclavian arteries, vertebral arteries, and intracranial circulation. Angiography enables the accurate assessment of collateral circulation. This is important because the presence of collateral circulation in medically treated patients with high-grade stenosis reduces the risk of ipsilateral stroke.
2. The risk of neurologic events during carotid angiography has historically been cited from as low as 0.5% for major events to as high as 4% for all events. In the hands of an experienced interventional cardiologist, the risk of stroke in one study was found to be approximately 0.5%. In our institution, 1 stroke was

observed in 580 consecutive diagnostic carotid catheterizations. Nonetheless, the risk–benefit ratio of performing carotid angiography must be carefully evaluated for each patient.

3. Two criteria are used to quantify carotid stenosis angiographically: the NASCET criteria and the European Carotid Surgery Trialists' (ECST) Collaborative Group criteria (Fig. 28.3). According to the NASCET criteria, the normal reference internal carotid diameter is the maximum diameter of the ICA distal to the lesion and distal to the carotid bulb. According to the ECST criteria, however, the normal reference diameter is determined by the estimated position of the external wall of the carotid bulb. The same lesion has a higher percentage of stenosis using the NASCET criteria compared with the ECST criteria. In addition, the NASCET criteria are difficult to apply in subtotal occlusions with collapse of the distal ICA due to underfilling. However, the NASCET criteria inherently have less variability and are now recommended as the standard for reporting of angiographic carotid stenosis in Medicare physician quality initiatives.
4. **Technique**
   a. Complete cerebral angiography involves angiography of the aortic arch and carotid arteries, intracerebral angiography, and angiography of the vertebral arteries and posterior circulation.
   b. A low-osmolar or iso-osmolar, nonionic, heparinized contrast agent should be used. In the absence of contraindications, the patient should be anticoagulated with 50 U/kg of intravenous heparin. The patient's head is often put in a holder or immobilizer to prevent inadvertent movement, and the patient is advised to look at the ceiling or keep his or her eyes closed. DSA should be used, if available, to improve resolution and minimize the amount of contrast needed. Before obtaining each cine angiogram, the patient should be instructed not to move, breathe, or swallow during image acquisition.
   c. Aortic arch angiography is performed using an angled pigtail catheter. Using a 0.035″ guidewire, the pigtail catheter is positioned in the mid-portion of the ascending aorta, and a cine angiogram of the aortic arch is obtained in a left anterior oblique projection (approximately 45°).
   d. Carotid angiography can be safely performed using a Judkins right (JR4) or a Headhunter catheter. Alternatively, a Vitek catheter can be used with

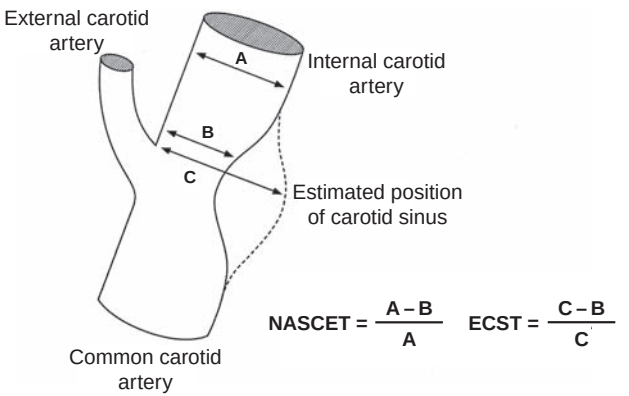

FIGURE 28.3 The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trialists' (ECST) Collaborative Group criteria for determining the degree of carotid stenosis.

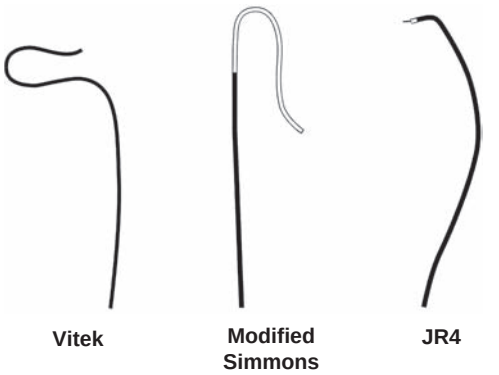

FIGURE 28.4 The three most common types of catheters used for carotid angiography.

bovine anatomy or type II or III arch. The Simmons catheter is useful in cases of severe tortuosity but requires reshaping in the aortic arch, which can lead to higher complication rates (Fig. 28.4). In the left anterior oblique projection, the JR4 catheter is positioned in the superior portion of the ascending aorta and rotated counterclockwise until it is positioned in the innominate artery. Nonselective cine angiography of the innominate, right subclavian, right carotid, and right vertebral arteries can then be performed with the image train in the right anterior oblique projection. In the right anterior oblique projection, a 0.035″ wire (e.g., Stiff-Angled Glide, Magic Torque, and Wholey) is used to advance the JR4 catheter to selectively engage the right common carotid. Two basic views should be obtained for each carotid: an ipsilateral oblique view (30° to 45°) and a cross-table lateral view. The table should be positioned so that the carotid bifurcation is in the middle of the screen, and shutters and filters should be used to optimize image quality.

e. For cerebral angiography, the patient's head is positioned in the center of the screen. Cine angiography is performed in the posteroanterior and lateral projections. It is important to continue the cine until the venous runoff has been captured to assess for intracranial arterial venous malformations and anomalous venous drainage. To selectively engage the left carotid, the catheter is positioned in the innominate artery so that the tip is pointing superiorly. The catheter is slowly pulled back, ensuring that the tip remains pointed superiorly, until the catheter tip exits the innominate and engages the left common carotid. The same views can then be obtained for the left carotid.

VI. MANAGEMENT OF CAROTID DISEASE

A. Medical management

1. Risk factor modification. Aggressive cardiovascular risk factor modification is recommended to reduce the risk of stroke and prevent the progression of existing disease, regardless of whether or not revascularization is indicated. Smoking cessation, blood pressure control to levels recommended by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC7) guidelines (< 140/90 mm Hg and more aggressive control in patients with atherosclerotic cardiovascular disease,

chronic kidney disease, or diabetes), control of diabetes (HbA1c < 7%), and lipid management (goal low-density lipoprotein [LDL] < 100 mg/dL, < 70 mg/dL if high CAD risk) are important treatment goals for which to strive in any patient with carotid disease.

2. **Antiplatelet therapy**
   a. The Antiplatelet Trialists' meta-analysis including 73,247 high-risk patients found that antiplatelet therapy as secondary prevention resulted in a 27% (25% attributed to aspirin) relative reduction in the combined end point of vascular death, MI, and stroke.
   b. **Aspirin** is the most extensively studied antiplatelet drug for the prevention of stroke and other cardiovascular events and should be initiated in all patients with evidence of carotid atherosclerosis. Men whose 10-year risk for the development of stroke or MI is ≥ 10% or greater should be started on low-dose (75 to 160 mg/day) aspirin for primary prevention. Women ≥ 65 years or older should be started on aspirin therapy (75 to 325 mg/day) for the primary prevention of MI and stroke. Aspirin therapy is also recommended in women younger than 65 years for the prevention of stroke when the benefits of ischemic stroke prevention outweigh the adverse effects of aspirin therapy.
   c. The **Clopidogrel** versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) trial demonstrated a decrease in the combined end point of vascular death, stroke, and MI with clopidogrel therapy compared with aspirin (5.32% vs. 5.83%) among patients with a history of stroke, MI, or symptomatic peripheral vascular disease. These data represented an 8.7% relative risk reduction ($p = 0.043$). Currently, there is no consensus on the use of clopidogrel for the primary prevention of stroke. Clopidogrel may be an option for the primary prevention of stroke in patients with moderate carotid stenosis who cannot tolerate aspirin.
   d. The Management of Atherothrombosis with Clopidogrel in High-Risk Patients with Recent Transient Ischemic Attacks or Ischemic Stroke (MATCH) study, which evaluated dual antiplatelet therapy with aspirin and clopidogrel versus clopidogrel alone in stroke patients with concomitant cardiovascular disease, patients who suffered a stroke while on a single antiplatelet agent, and patients with severe aortic arch disease, demonstrated an insignificant trend toward improved efficacy with dual antiplatelet therapy; however, there was a highly significant increase in life-threatening bleeding events.
   e. In contrast to MATCH, the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial evaluated aspirin plus clopidogrel versus aspirin alone in patients with symptomatic cardiovascular disease or a constellation of cardiovascular risk factors. In this patient population, the combination of aspirin and clopidogrel was not more effective than aspirin alone in reducing the rate of MI, stroke, or death from cardiovascular causes. Dual antiplatelet therapy did improve rates of all-cause stroke (2.4% vs. 1.9%, $p = 0.05$), and subgroup analyses showed a significant 12.5% relative reduction in the risk of primary events in patients with established cardiovascular disease. As will all subgroup analyses, however, these results should be interpreted with caution.
   f. Low-dose aspirin (25 mg twice daily) plus dipyridamole (200 mg twice daily) has been found to be more beneficial than aspirin alone or dipyridamole alone for the secondary prevention of stroke in the European Stroke Prevention Study 2 (ESPS 2). Similarly, in the European/Australian Stroke Prevention in Reversible Ischemia Trial (ESPRIT), extended-release dipyridamole administered with aspirin was superior to aspirin alone in the prevention of MI, stroke, or vascular death.

g. The Prevention Regimen for Effectively avoiding Second Strokes (PRoFESS) trial, which enrolled over 20,000 patients with noncardioembolic ischemic stroke, showed that clopidogrel monotherapy and aspirin plus extended-release dipyridamole have similar risks and benefits for secondary stroke prevention. There was no difference between treatment with aspirin plus extended-release dipyridamole or clopidogrel for the primary outcome of recurrent stroke or the composite secondary outcome of stroke, MI, or vascular death. However, despite the nearly identical event rates, the trial failed to meet the prespecified noninferiority criteria for treatment with aspirin and extended-release dipyridamole.

h. According to the American Heart Association (AHA)/American Stroke Association (ASA) Guidelines for the Prevention of Stroke in Patients with Ischemic Stroke or TIA, the accepted treatment strategies for the secondary prevention of noncardioembolic stroke include one of the following:
(1) Aspirin (50 to 100 mg daily)
(2) Aspirin (25 mg) and extended-release dipyridamole (200 mg twice daily)
(3) Clopidogrel (75 mg daily), especially for patients with aspirin allergy or resistance

3. Antihyperlipidemic agents

a. Epidemiologic data have shown higher stroke rates among patients with high LDL and low high-density lipoprotein cholesterol levels. Several studies have consistently shown carotid plaque regression in patients treated with statins, and clinical trials have shown a reduction in stroke among patients treated with statins. In the Scandinavian Simvastatin Survival Study (4S), nonembolic strokes were significantly reduced in the statin arm. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) study demonstrated a 16% relative risk reduction in stroke with statin therapy in 4,731 patients with prior stroke or TIA randomized to atorvastatin versus placebo. In a meta-analysis of randomized trials that included a total of 165,792 patients with hyperlipidemia, each 39 mg/dL reduction in LDL cholesterol equates to a reduction in relative risk of stroke of 21.1%.

b. The beneficial effects of statins in reducing strokes are highest among patients at the highest risk for stroke. For primary prevention, all high-risk patients (e.g., diabetes, peripheral vascular disease, and CAD) should be treated with statins. For secondary prevention, all patients with a history of MI, TIA, and stroke should be on statin therapy.

4. Antihypertensive agents

a. Hypertension is the single most modifiable risk factor in the prevention of stroke, and epidemiologic data suggest that approximately 60% of all strokes are attributable to hypertension. Several randomized controlled trials have shown benefit of a variety of antihypertensive agents, ACE inhibitors, and diuretics in particular. The Heart Outcomes Prevention Evaluation (HOPE) study showed a relative risk reduction of 32% for stroke in patients with known risk or at high risk for cardiovascular disease treated with ramipril versus placebo. The Perindopril Protection Against Recurrent Stroke Study (PROGRESS) showed a 43% reduction in stroke in patients with prior strokes with the use of perindopril versus placebo. The Antihypertensive and Lipid-lowering Treatment to Prevent Heart Attack Trial (ALL-HAT) showed that thiazide diuretics were superior to lisinopril for prevention of stroke in patients with hypertension and one other coronary heart disease risk factor (risk of stroke: risk ratio [RR] 1.15, 95% confidence interval [CI] 1.02 to 1.30). In the Losartan Intervention for Endpoint Reduction (LIFE) study, the angiotensin receptor blocker losartan was associated with a 40% reduction in stroke compared with atenolol.

b. The JNC7 guidelines recommend that all patients with prehypertension (systolic blood pressure 120 to 139 mm Hg or diastolic blood pressure 80 to 89 mm Hg) undergo lifestyle modifications to lower blood pressure. Furthermore, all patients with blood pressure > 140/90 mm Hg (or > 130/80 mm Hg with diabetes or chronic kidney disease) should receive antihypertensive drug therapy to achieve their blood pressure goal. ACE inhibitors and diuretic agents remain first-line therapy in patients with cerebrovascular disease.

5. Anticoagulation

a. There are no data specifically addressing the use of warfarin for primary stroke prevention in patients with documented carotid stenosis. However, one study has suggested that **low-dose warfarin may attenuate carotid plaque progression** in men. The use of warfarin for the secondary prevention of noncardioembolic strokes (including patients with carotid stenosis) is controversial. There was no clear benefit for low- and medium-dose oral warfarin therapy (international normalized ratio [INR] 2.0 to 3.0) for the secondary prevention of noncardioembolic stroke in the Warfarin–Aspirin Symptomatic Intracranial Disease (WASID) trial and a significant increase in adverse effects, including death, major hemorrhage, and MI, with warfarin use. High-dose warfarin (INR 3.0 to 4.5) for the secondary prevention of noncardioembolic stroke results in a high rate of bleeding complications, including hemorrhagic stroke, and should not be used.

B. Surgical management: carotid endarterectomy (CEA)

CEA is the standard of care for the reduction of stroke or TIA in patients with high-grade symptomatic or asymptomatic carotid stenosis. Several trials have firmly established the utility of CEA in preventing stroke in the presence of severe carotid stenosis as compared with medical therapy. It is important to keep in mind that high-risk patients were not enrolled in these trials. Because the risk of surgery among such patients probably would be higher than reported in these trials, extrapolation of these data to high-risk patients must be done with caution.

1. Major trials

a. Asymptomatic, low-risk patients

(1) Asymptomatic Carotid Atherosclerosis Study (ACAS)

(a) A total of 1,662 patients with asymptomatic carotid stenosis of 60% or more were randomized to CEA or medical therapy. All patients were treated with aspirin (325 mg daily).

(b) At a median of 2.7 years of follow-up, the estimated 5-year risk of stroke or death was 5.1% in the surgical arm and 11% in the medically treated arm ($p = 0.004$). The annual risk of stroke among patients in the medical arm was 2.3%. The perioperative stroke or death rate was 2.3%.

(2) Veterans Affairs Asymptomatic Carotid Stenosis Study

(a) In this study, 444 men with 50% or more carotid stenosis were randomized to CEA or to medical therapy with aspirin.

(b) The incidence of ipsilateral stroke was 4.7% in the surgical group versus 9.4% in the medical group, but there were no significant differences between the surgical and medical groups for all strokes and deaths (surgical 41.2% vs. medical 44.2%; RR 0.92, 95% CI 0.68 to 1.22).

(3) Asymptomatic Carotid Surgery Trial

(a) In this trial, 3,120 patients with > 60% carotid stenosis were randomized to immediate CEA plus medical treatment versus medical treatment and deferred CEA.

(b) The risk of perioperative stroke or death within 30 days of CEA was 3.1%. The estimated 5-year risks of stroke were 6.4% versus 11.8%, $p < 0.001$, for immediate CEA versus deferred CEA.

b. Symptomatic, low-risk patients

(1) The NASCET randomized 2,926 patients with symptomatic carotid stenosis (30% to 99%) to either medical therapy or medical therapy plus CEA. Recruitment of patients with severe carotid stenosis (70% to 99%) was stopped after 659 patients due to highly beneficial effect of CEA.

(a) A total of 659 patients with severe carotid stenosis (70% to 99%), ipsilateral hemispheric or retinal TIA, amaurosis fugax, or nondisabling stroke within 120 days were randomized to CEA or medical therapy.

(b) For those with severe (70% to 99%) carotid stenosis, the 30-day risk of stroke or death was 3.3% in the medical group and 5.8% in the surgical group. Two-year risk of any stroke was 26% in the medical group and 9% in the surgical group ($p < 0.001$), and the risk of major stroke or death was 18.1% in the medical group and 8% in the surgical group ($p < 0.001$). Patients with the most severe stenoses had the most benefit.

(c) A total of 2,267 patients with 30% to 69% stenosis, ipsilateral hemispheric or retinal TIA, or nondisabling stroke within 120 days were randomized to CEA or medical therapy. Patients with 50% to 69% stenosis had a 5-year stroke rate of 22.2% in the medical group and 15.7% in the surgical group ($p = 0.045$). Patients with 30% to 49% stenosis had a 5-year stroke rate of 18.7% in the medical group and 14.9% in the surgical group ($p = 0.16$).

(2) Veterans Affairs Cooperative Study

(a) In the Veterans Affairs Cooperative Study, 189 men with > 50% internal carotid stenosis with ipsilateral symptoms were randomized within 120 days of a neurologic event to CEA or medical therapy.

(b) At a mean of 11.9 months' follow-up, the incidence of stroke or TIA was 19.4% in the medical arm and 7.7% in the surgical arm ($p = 0.011$). The 30-day stroke or death rate was 6.6% in the surgical group and 2.2% in the medical group.

(3) The ECST Collaborative Group

(a) A total of 2,518 patients with symptomatic carotid stenosis were randomized to CEA or medical therapy. Patients ($n = 374$) with mild stenosis (0% to 29%) had low rates of ipsilateral stroke overall, and 3-year benefits of surgery were small and outweighed by operative risk. The ipsilateral stroke rate at 3 years of follow-up for patients with stenoses between 70% and 99% ($n = 778$) was 16.8% in the medical arm and 10.3% in the surgical arm.

2. Complications and management of patients after CEA

a. Major complications of CEA include MI, stroke, and death. Other complications include bleeding and wound hematoma, cranial nerve injury, wound infection, bradycardia, hyper- or hypotension, and, rarely, seizures and intracerebral hemorrhage.

b. After CEA and in the absence of contraindications, all patients should be treated with antiplatelet therapy.

3. The ASA/American College of Cardiology Foundation (ACCF)/AHA recommendations for CEA

a. Patients at average or low surgical risk who experience nondisabling ischemic stroke or transient cerebral ischemic symptoms, including hemispheric events or amaurosis fugax, within 6 months (symptomatic patients) should undergo CEA if the diameter of the lumen of the ipsilateral ICA is reduced > 70% as documented by noninvasive imaging or > 50% as documented by catheter angiography and the anticipated rate of perioperative stroke or mortality is < 6%.

b. Selection of asymptomatic patients for carotid revascularization should be guided by an assessment of comorbid conditions, life expectancy, and other individual factors and should include a thorough discussion of the risks and benefits of the procedure, with an understanding of patient preferences. It is reasonable to perform CEA in asymptomatic patients who have > 70% stenosis of the ICA if the risk of perioperative stroke, MI, and death is low.

c. Except in extraordinary circumstances, carotid revascularization is not recommended when atherosclerosis narrows the lumen by < 50%.

4. Combined CEA and coronary artery bypass grafting (CABG)

a. Patients with severe coronary disease may have severe carotid disease, and surgery in this population is a high-risk procedure. The optimal treatment strategy remains unclear.

b. Options include simultaneous CEA and CABG, staged CEA followed by CABG, or staged CABG followed by CEA. In staged procedures, CEA first increases risk of perioperative MI, and CABG first increases risk of perioperative stroke.

c. Some investigators have reported better results with simultaneous procedures, but patient selection is likely an important factor in achieving satisfactory outcomes. A meta-analysis of 16 studies with a total of 844 combined procedure and 920 staged procedure patients reported a higher risk of death, stroke, or MI among patients undergoing combined compared with staged procedures. Percutaneous intervention may be a better choice for this patient population, and this is an area that requires further investigation.

C. Percutaneous carotid intervention

1. Since the first description of carotid angioplasty in 1980, a number of registry studies and trials have been published reporting high rates of procedural success. However, percutaneous carotid angioplasty is rarely performed as a stand-alone procedure because of unacceptably high rates of recoil, restenosis, and adverse procedural outcomes due to distal embolization. Carotid stenting has become the standard of care for patients undergoing percutaneous carotid intervention.

2. Compared with angioplasty alone, carotid stenting improves procedural success rates, decreases periprocedural complications (including carotid artery dissection), and decreases restenosis. Several types of embolic protection devices are in use to prevent embolic complications of angioplasty and stenting. Results of observational studies have shown that embolic protection devices can reduce rates of adverse events during carotid artery stenting in experienced hands; however, inexperience can also worsen clinical outcomes when these devices are used. Benefit of these devices to prevent periprocedural events has not been established in randomized controlled trials.

3. Several manufacturers have stents approved for use in the carotid artery. Balloon-expandable stents are generally not used for carotid stenting because of the potential for structural deformation that can occur as a result of external forces such as those caused by neck movement. Self-expanding stents, such as the Wallstent (Boston Scientific Corp, Quincy, MA), Acculink carotid stent (Abbott Vascular Devices, Redwood City, CA, formerly Guidant Corp), Xact carotid stent (Abbott Vascular Devices, Redwood City, CA), and the carotid SMART stent (Cordis Endovascular, Warren, NJ), are commonly used, as they continue to exert outward radial force after deployment and resist crushing.

4. Trials

a. The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) compared carotid angioplasty (without stenting) with CEA among patients with > 50% carotid stenosis and found similar rates of procedural bleeding, major stroke, or death between the two treatment strategies

at 30 days and 1 year. However, the CEA cohort did have a higher number of patients whose surgery was complicated by cranial nerve injury.

b. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial was the first multicenter, randomized, controlled trial comparing carotid stenting with CEA in high-risk patients. Using the PRECISE nitinol stent (Cordis, Warren, NJ) and the AngioGuard (Cordis, Warren, NJ) distal protection device, 334 patients were randomized (167 to carotid stenting and 167 to CEA). An additional 409 patients were enrolled in a stent registry. The combined end point of death, stroke, and MI at 1 year was reached in 12.2% of patients in the stenting arm and 20.1% of patients in the CEA arm (p = 0.004 for noninferiority and p = 0.053 for superiority). This is the first randomized trial to show noninferiority of carotid stenting compared with CEA.

c. The Carotid Revascularization Using Endarterectomy or Stenting Systems (CARESS) trial was a phase I multicenter, prospective randomized trial comparing carotid stenting with CEA in a broad-risk group of symptomatic (with > 50% stenosis) and asymptomatic patients (with > 75% stenosis). The combined primary end point of stroke and death was 3.6% for CEA and 2.1% for carotid stenting at 30 days, and 13.6% for CEA and 10.0% for carotid stenting at 1 year. The authors concluded that carotid stenting was equivalent to CEA in both symptomatic and asymptomatic patients at 1 year.

d. The Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE) trial was a multinational, multicenter randomized trial evaluating carotid stenting with optional distal embolic protection versus CEA in 1,200 patients with symptomatic carotid artery stenosis. Unlike the SAPPHIRE trial, the SPACE trial was not limited to high-risk surgical patients. The SPACE trial was unable to demonstrate noninferiority of carotid stenting compared with CEA, as the rate of death or ipsilateral ischemic stroke at 30 days from procedure was 6.84% with carotid stenting versus 6.34% with CEA (p = 0.09). A criticism of the SPACE trial was that embolic protection devices were not required and were only utilized in 27% of the cases. However, no significant difference in the primary end point was observed with or without the use of embolic protection devices.

e. The Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S) trial was a multicenter, randomized, noninferiority trial comparing carotid stenting with CEA in symptomatic patients with 60% to 99% carotid stenosis. The EVA-3S trial enrolled moderate-risk surgical patients. EVA-3S was stopped prematurely after enrollment of 527 patients, due to higher rates of stroke and death at 1 month (9.6% vs. 3.9%, p = 0.01) and 6 months (11.7% vs. 6.1%, p = 0.02) with carotid stenting versus CEA. A criticism of the EVA-3S trial was the lack of experience of the operators taking part in the study, as the interventionalists were required to have completed only two procedures with any device prior to its use in the trial. Furthermore, the use of embolic protection devices was optional at the onset of the trial, and a significant difference in the 30-day outcome of stroke and death was present between patients treated with and without embolic protection devices (7.9% vs. 25%, respectively). The use of embolic protection devices during carotid artery stenting did not significantly improve rates of stroke or death versus CEA.

f. The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) randomly assigned 2,502 patients with carotid atherosclerotic disease (47% asymptomatic, 53% symptomatic) to CEA or stenting. The primary end point of the trial, a composite of any stroke, MI, or death within

30 days following treatment plus any ipsilateral stroke during long-term follow-up (median 2.5 years), was similar for stenting and CEA (7.2% vs. 6.8%, respectively; $p = 0.51$). For patients aged 70 years or older, the rates of the primary end point and adverse events increasingly favored surgery over stenting. A secondary analysis showed that for the subgroup of patients with symptomatic carotid disease, the periprocedural rate of stroke and death was significantly higher for those assigned to stenting compared with CEA (6% vs. 3.2%, respectively; $p = 0.02$). However, for both stenting and CEA, the rates of stroke and death were at or below those of previous randomized controlled trials and were within the complication thresholds suggested in current guidelines for symptomatic and asymptomatic patients.

g. In the International Carotid Stenting Study (ICSS, also known as CAVATAS 2), 1,713 patients with recently symptomatic carotid stenosis, suitable for either surgery or percutaneous intervention, were randomly assigned to treatment with either CEA or stenting. All patients had carotid artery stenosis of > 50% by NASCET criteria on noninvasive imaging. At 120 days, the proportion of patients who reached the combined end point of stroke, death, and MI was significantly higher for the stenting group than for the CEA group (8.5% vs. 5.2%, respectively; $p = 0.006$). Longer term follow-up of this patient group is currently pending.

5. Complications and management

a. The major periprocedural complications during carotid stenting are stroke, MI, and death. Other complications include TIAs, access site bleeding, bradycardia, hypotension, seizures, and intracranial hemorrhage. **Advanced age and long or multiple stenoses have been found to be independent predictors of periprocedural stroke**. In one study, stenting in the presence of a contralateral occlusion, stenting after a previous CEA, or combined carotid and coronary interventions **did not** increase the risk of adverse outcomes.

b. Periprocedural cerebrovascular events occur largely because of embolization of plaque debris and thrombus into the cerebral circulation during manipulation of the carotid plaque. Such emboli have been documented by the use of transcranial Doppler, and the amount of embolization has been correlated with the size of infarct during CEA. Emboli protection devices decrease the volume of distal embolization.

c. Embolic protection devices fall into three general categories (Figs. 28.5 and 28.6): distal occlusion balloon protection, distal filter, and proximal occlusion balloon. The PercuSurge GuardWire (Medtronic, Minneapolis, MN) system provides occlusion of distal flow during carotid stenting, enabling the removal of embolized debris (Fig. 28.5). The AngioGuard (Cordis, Warren, NJ) is one example of a filtration umbrella mounted on a 0.014″ guidewire, which is positioned distal to the plaque during stenting (Fig. 28.6). At the end of the procedure, the filter is removed using a retrieval catheter. Proximal occlusion balloon systems create reversal of flow in the ICA, preventing embolization of debris into the cerebral vasculature.

d. **Bradycardia and hypotension** occur often during carotid stenting because of instrumentation and stretching of the carotid sinus baroreceptors. These hemodynamic effects are usually transient but can persist for up to 24 hours after intervention. **Symptomatic patients** should be managed with **intravenous crystalloid infusion and potentially a low-dose infusion of an inotropic agent (e.g., dopamine) or temporary pacing as required**. Unless the patient is hypertensive, antihypertensive and negative inotropic medications are usually withheld immediately preprocedure and postprocedure. Telemetry monitoring should be continued for 24 hours, and the nursing staff should perform frequent neurologic checks postprocedure. All patients

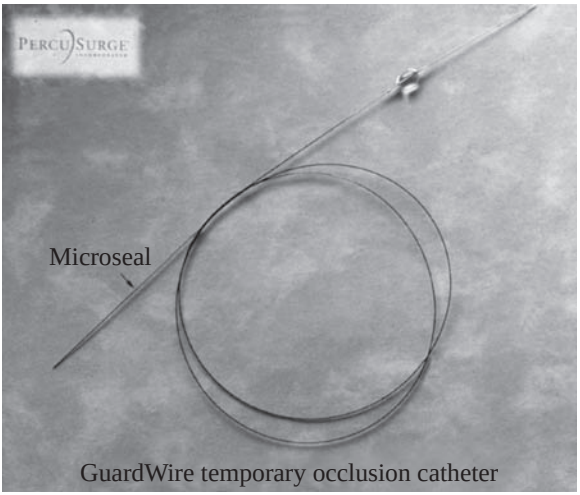

FIGURE 28.5 The PercuSurge GuardWire (Medtronic, Minneapolis, MN) system.

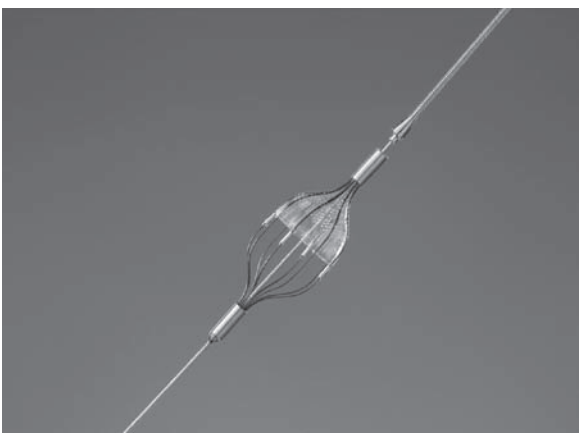

FIGURE 28.6 The AngioGuard (Cordis, Warren, NJ) emboli protection device.

should undergo a thorough and well-documented neurologic examination before and after the procedure. Standardized stroke scales are often utilized (e.g., NIHSS, Barthel, and modified Rankin).

e. **Hyperperfusion syndrome**, manifested by strokelike symptoms and signs, can occur because of the rapid return of flow to a chronically underperfused cerebral vascular bed, with resultant disordered autoregulation. Risk factors include **severe hypertension, critical carotid stenosis, and contralateral carotid occlusion**. Cerebral hemorrhage is a dreaded complication of the hyperperfusion syndrome.

f. Patients undergoing carotid stenting should be pretreated with aspirin (325 mg daily) and clopidogrel (75 mg twice daily) for 2 days before the procedure if possible. After the procedure, **lifelong aspirin therapy should be instituted**, and **clopidogrel (75 mg daily) should be continued for at least 6 weeks**. For patients with recurrent symptoms or a history of neck irradiation, clopidogrel should be continued indefinitely. The incidence of restenosis after carotid stenting is lower than after coronary stenting and ranges between 1% and 6% per year.

g. The routine use of adjunctive glycoprotein (GP) IIb/IIIa inhibitors has not been well studied in the setting of carotid stenting. Initial observational data suggest that their use may be safe. However, because of the potential for intracranial hemorrhage, especially among patients with hypertension or hyperperfusion syndrome after carotid stenting, and without clear evidence of benefit, GP IIb/IIIa inhibitors are not routinely used. Further studies are needed to better define the use of these agents in this arena; however, incremental benefit above and beyond the use of mechanical embolic protection devices may be difficult to demonstrate.

h. Patients with carotid stenosis frequently have concomitant CAD. Successful combined carotid stenting and percutaneous coronary intervention has been reported as a simultaneous procedure, and the two are frequently performed as staged procedures with satisfactory outcomes.

6. The ASA/ACCF/AHA recommendations for carotid stenting

a. Carotid stenting is an indicated alternative to CEA for symptomatic patients at average or low risk of complications associated with endovascular intervention when the diameter of the lumen of the ICA is reduced by > 70% by noninvasive imaging or > 50% by catheter angiography and the anticipated rate of periprocedural stroke or mortality is < 6%.

b. It is reasonable to choose carotid artery stenting over CEA when revascularization is indicated in patients with neck anatomy unfavorable for arterial surgery.

c. Prophylactic carotid artery stenting might be considered in highly selected patients with asymptomatic carotid stenosis (minimum 60% by angiography and 70% by validated Doppler ultrasound), but its effectiveness compared with medical therapy alone in this situation is not well established.

Richard A. Krasuski

Atrial Septal Defect and Patent Foramen Ovale

I. INTRODUCTION

A. Atrial septal defects (ASDs) constitute approximately 5% to 10% of congenital heart disease. Excluding bicuspid aortic valve and mitral valve prolapse, ASD is the most common form of congenital heart defect found among adults and is the most common acyanotic shunt lesion in adults as well.

B. Often, an atrial communication may go unrecognized into adulthood because the clinical symptoms and physical manifestations can be subtle.

C. Although survival into adulthood is the rule, the overall life expectancy is decreased in patients with an unrepaired ASD. Long-term exposure to chronic right heart volume overload can have deleterious effects, such as atrial arrhythmias, pulmonary vascular disease, and right heart failure. These clinical findings are directly related to patient age, with almost all patients becoming symptomatic by the fifth or sixth decade. The presence of an atrial communication is also a potential source of paradoxical embolus.

D. A patent foramen ovale (PFO) is a specific form of interatrial communication caused by incomplete closure of the foramen ovale after birth. PFOs are present in 25% to 30% of the general population. The prevalence of PFO in patients with cryptogenic stroke is approximately 40% to 50%.

E. Atrial septal aneurysms are congenital outpouchings of the atrial septum, near the fossa ovalis. These can perforate, resulting in an ASD with left-to-right shunting of blood. Atrial septal aneurysms can be detected in up to 10% of patients undergoing echocardiography and in up to 30% of patients with cryptogenic stroke, generally with a concomitant PFO.

II. ANATOMY AND EMBRYOLOGY.

The primitive atrium is first partitioned into right and left atria by growth of the septum primum—a thin, crescent-shaped membrane that grows from the roof of the primitive atrium toward the endocardial cushions located between the atria and ventricles. An atrial communication initially persists as the foramen primum, composed of the free edge of the septum primum and the endocardial cushions. Before closure of the foramen primum, fenestrations develop in the septum primum that coalesce to form the ostium secundum. As the septum primum then fuses with the endocardial cushions, the ostium secundum maintains a right-to-left atrial flow that is important in the fetal circulation. **Failure of this fusion results in the development of a primum ASD**. A second septum, the septum secundum, then forms to the right of the septum primum, growing toward the endocardial cushions and usually closing the ostium secundum. **Failure to close the ostium secundum results in the formation of a secundum ASD**.

The septum secundum forms an incomplete partition of the atria, leaving a foramen ovale (i.e., fossa ovalis). The remaining septum primum tissue on the left atrial (LA) side

becomes a flap valve, or valve of the foramen ovale, and allows for the continued right-to-left shunting in the fetal circulation. At birth, when LA pressure increases, the septum primum flap closes and eventually fuses to anatomically seal the atrial septum. A "true ASD" results from a deficiency in septal development or from resorption of atrial tissue, whereas a **PFO results from failure of this septum primum flap to adequately seal the fossa ovalis**. At autopsy, a "probe-patent" PFO remains in 25% to 30% of patients.

During development, if there is overabundant or weakened septal tissue, the septum becomes very mobile. This can be visualized during echocardiography, and the degree of excursion can be measured. If the maximal excursion of the interatrial septum is **15 mm or more**, this abnormality is called an **atrial septal aneurysm**. If the amount of septal excursion is < 15 mm, it is referred to as a redundant atrial septum.

ATRIAL SEPTAL DEFECTS

I. ASD TYPES (Fig. 29.1)

A. Ostium secundum defects or **secundum ASDs** constitute the most common type, accounting for 70% to 75% of ASDs. This defect, a true defect of the atrial septum, is located in the midportion of the atrial septum, within or including the fossa ovalis. Defects result from a deficient septum primum or an abnormally large foramen secundum. This type of ASD is two times more common in female patients. Isolated secundum ASD has been associated with mitral valve prolapse and other forms of congenital heart disease. It may also be associated with rheumatic mitral stenosis (i.e., Lutembacher syndrome).

B. Ostium primum defects or **primum ASDs** account for 15% to 20% of ASDs and are part of the spectrum of atrioventricular (AV) septal defects (also known as AV canal defects or endocardial cushion defects). These defects occur in the inferior–anterior portion of the atrial septum and are frequently associated with a cleft in the anterior leaflet of the mitral valve, leading to varying degrees of mitral regurgitation. In their complete form, they include a large ventricular septal defect and a common

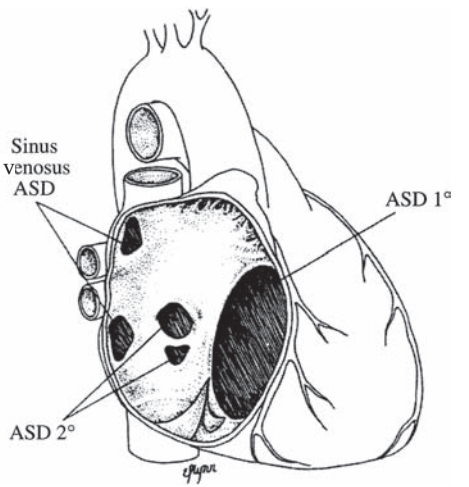

FIGURE 29.1 Diagrammatic representation of common atrial septal defects. ASD, atrial septal defect; 1°, primum; 2°, secundum. Reproduced from Fyler DC, ed. *Nadas Pediatric Cardiology.* Philadelphia, PA: Hanley & Belfus; 1992, with permission.

AV valve. Depending on the severity of dysfunction of the mitral valve, these patients may become symptomatic at a young age. This defect in the inlet septum is the most common ASD associated with Down's syndrome.

C. **Sinoseptal** defects constitute the remaining 5% to 10% of septal defects. Distinct from the true ASDs described previously, these lesions involve the portion of the atrial wall derived from the sinus venosus (i.e., there is no direct communication between the right and left atria). **Sinus venosus defects** are typically at the orifice of the superior vena cava (SVC) at the junction of the right atrium or, less frequently, in the region of the inferior vena cava (IVC). These sinus venosus defects are frequently associated with partial anomalous pulmonary venous drainage of the right pulmonary veins and require a high index of suspicion for diagnosis because they are generally not visualized by standard transthoracic echocardiography (TTE). Transesophageal echocardiography (TEE) is generally required for visualization in adults. Magnetic resonance imaging (MRI) or computed tomography may also be used for diagnosis. These defects should be considered in any patient with unexplained right atrial (RA) or right ventricular (RV) dilation. An uncommon sinoseptal defect is the partially or completely **unroofed coronary sinus**, which is located inferior and slightly anterior to the fossa ovalis. These defects are commonly associated with other forms of congenital heart disease, such as complete AV septal defect, or can be associated with an absence of coronary sinus and a left SVC that drains into the left atrium.

II. PATHOPHYSIOLOGY. The magnitude and direction of the shunt through the ASD depend on the size of the defect as well as the diastolic filling properties of the ventricles. Any condition that causes reduced left ventricular (LV) compliance, such as LV hypertrophy or LV scar, or increased LA pressure, such as mitral stenosis, will increase the degree of left-to-right shunting. Conversely, conditions that cause reduced RV compliance, such as pulmonary hypertension or pulmonary stenosis, or increased RA pressure, such as tricuspid stenosis, will reduce the degree of left-to-right shunting and, in some instances, even lead to shunt reversal. In general, the ASD must be at least 10 mm in its greatest dimension to cause a significant shunt, although this can be hard to measure, as most ASDs are not circular. A left-to-right shunt is considered significant when the ratio of pulmonary-to-systemic blood flow, or shunt fraction (Q_p/Q_s), is > 1.5:1.0 or when right heart chamber dilation is present.

III. CLINICAL MANIFESTATIONS. The clinical presentation of a patient with an ASD results from the effects of long-term left-to-right shunting and subsequent volume loading of the right heart. The age at which the symptoms occur is variable and does not necessarily depend on the size of the defect.

A. **Exercise intolerance** with **fatigue** and **dyspnea** may occur, but it is frequently not appreciated by the patient until after the defect has been closed. Late findings include **supraventricular arrhythmias**, such as atrial fibrillation or flutter, severe irreversible **pulmonary vascular disease**, and, eventually, **right heart failure**. Occasionally, a **paradoxical embolus** causing a stroke or transient ischemic attack (TIA) is the first clue to an ASD.

B. The physical findings may include a hyperdynamic cardiac impulse, the characteristic **widely or fixed split second heart sound**, and a **soft systolic murmur at the second left intercostal space** due to increased flow across the pulmonary valve. If the shunt is more than a shunt fraction (Q_p/Q_s) of 2.5:1, there may be a diastolic murmur secondary to increased flow across the tricuspid valve. A loud P_2 component of the second heart sound indicates the presence of pulmonary hypertension, which can affect up to 20% of patients; if cyanosis is present, this generally suggests advanced pulmonary hypertension with reversal of shunt flow (**Eisenmenger syndrome**). An important clue to the presence of Eisenmenger syndrome is an oxygen saturation that does not significantly improve with supplemental oxygen.

Another physical examination finding that may be encountered is a holosystolic murmur characteristic of mitral regurgitation, which is often heard in a patient with a primum ASD.

IV. LABORATORY EXAMINATION

A. Electrocardiogram (ECG). The ECG can provide clues to the possibility of an ASD. The rhythm may be sinus, but may also be atrial fibrillation or atrial flutter. Inverted P waves in the inferior leads suggest an absent or nonfunctional sinus node, as may be seen with a sinus venosus defect.

1. **Secundum ASD**
   - **(a)** RSR' pattern in lead V_1
   - **(b)** QRS duration < 0.11 seconds (incomplete right bundle branch block)
   - **(c)** Right-axis deviation
   - **(d)** RV hypertrophy
   - **(e)** First-degree AV block (20%)
   - **(f)** RA enlargement (about 50%) with a prominent P wave in lead II
2. **Primum ASD**
   - **(a)** RSR' pattern in lead V_1
   - **(b)** Left-axis deviation
   - **(c)** First-degree AV block, classically seen with right bundle branch block and left anterior fascicular block

B. Chest radiography may reveal cardiomegaly due to right heart enlargement. With large left-to-right shunts, the central pulmonary arteries and vascular markings may appear prominent. In the setting of advanced pulmonary vascular disease, however, the pulmonary arteries may appear large but have oligemic peripheral lung fields, so-called vascular pruning.

V. DIAGNOSTIC STUDIES

A. Echocardiography is the primary means by which an ASD is diagnosed. TTE can document the size of the defect as well as the direction of the shunt flow and occasionally the location of the pulmonary veins in the younger patient. In the adult, transesophageal studies are generally required for a full anatomic assessment. An ASD should be suspected when right-sided chamber enlargement is noted on echocardiography and no other cause is identified.

1. Typical transthoracic views for imaging an ASD include the parasternal short-axis view, the apical four-chamber view, and the subcostal coronal and sagittal views. Findings include RA and RV enlargement, which indicate a functionally important defect. An estimate of RV pressure should be made via the jet of tricuspid insufficiency, and evidence for RV pressure and volume overload should be noted via observation of septal motion in systole and diastole, respectively. Evidence of left-to-right (or right-to-left) shunting across the defect should be demonstrated using color Doppler techniques. Evidence of RA and RV enlargement in the absence of an obvious cause on echocardiography, such as tricuspid regurgitation or an ASD, should prompt a search for a sinus venosus defect and/or partial anomalous pulmonary venous drainage. Intravenous contrast (i.e., agitated saline) and TTE can identify a shunt, but TEE is usually required to demonstrate a sinus venosus defect. Of note, in isolated partial anomalous pulmonary venous return, the intravenous contrast study will be negative.
2. TEE is usually required in the adult patient for further anatomic definition and to determine whether the defect is amenable to percutaneous closure. Contrast studies with agitated saline are helpful in confirming the presence and location of atrial shunting. The midesophageal four-chamber and bicaval views are preferred, with injection of agitated saline through an upper extremity vein. Injection into the left arm may be particularly helpful to establish the presence of a

persistent left SVC that drains into the coronary sinus or directly into the left atrium. In the diagnosis of a sinus venosus defect, care must be taken to evaluate the location of the pulmonary veins for evidence of anomalous drainage.

B. Cardiac catheterization is typically not required for diagnostic purposes except to assess pulmonary pressures and resistance, to assess for coronary artery disease before planned surgical closure in the adult patient, or as part of a planned transcatheter device closure. Right heart catheterization can be performed in most cases using a standard end-hole catheter. The lateral camera is helpful in directing the catheter posterior before advancing across the ASD. Our standard is to perform a complete right heart catheterization, including oximetry measurements and hemodynamic assessment.

1. Oximetry samples obtained during catheterization demonstrate a step-up within the right atrium due to shunting across the defect. Careful interrogation of innominate vein saturation and SVC saturation is important to exclude a step-up at the SVC level that would support the existence of associated partial anomalous pulmonary venous drainage. Desaturation in the left atrium systemically confirms right-to-left shunting and should prompt further investigation of RV and pulmonary artery pressures. Other diagnoses producing a similar picture include large ventricular septal defects with tricuspid regurgitation, partial or complete AV canal defects, or systemic arteriovenous fistulas.

   The significance of the defect can be assessed by calculating the **shunt fraction (Q_p/Q_s)**, which is the ratio of pulmonary blood flow (Q_p) to systemic blood flow (Q_s). Oximetry values, obtained during right heart catheterization and used previously to determine if a step-up is present, can be helpful for shunt calculation as follows:

$$Q_p/Q_s = \frac{\text{aortic saturation} - \text{mixed venous saturation}}{\text{pulmonary vein saturation} - \text{pulmonary artery saturation}}$$

   The mixed venous saturation is obtained in the setting of an ASD by multiplying the SVC saturation by 3, adding the IVC saturation, and then dividing the sum by 4. If the pulmonary vein saturation is not directly measured, it can be assumed in the absence of considerable lung disease to be 95%.

2. Hemodynamic assessment may reveal modest elevations in RV and pulmonary artery pressures. An important assessment is comparison of pulmonary artery pressure with systemic pressure and measurement of pulmonary vascular resistance. If pulmonary pressures are elevated, the response to oxygen or other vasodilators should be assessed. Alternatively, the ASD can be balloon occluded with assessment of hemodynamics to ensure that closure is safe. Examples of the usual catheterization findings with and without pulmonary vascular disease are illustrated in Figure 29.2.

   Using a derivative of Ohm's law, $P = Q \times R$, an ASD will increase the flow (Q) to the lungs, and, therefore, increase the pulmonary pressure (P) without a significant change in resistance (R). Findings that may preclude eventual ASD closure include one or more of the following: pulmonary vascular resistance more than one-half of the systemic vascular resistance or an indexed pulmonary vascular resistance > 7 Wood units/m^2.

3. Angiography is typically not necessary for diagnostic purposes. Some transcatheter closure device protocols include angiography, typically performed in the right pulmonary vein or levophase from a main pulmonary artery injection in the left anterior oblique and cranial projections. This may be an important way to confirm the absence of additional defects, such as partial anomalous pulmonary venous drainage, before proceeding with transcatheter device closure.

C. Cardiac MRI can be helpful, as it can provide additional information beyond echocardiography. MRI provides an excellent assessment of RV size and function,

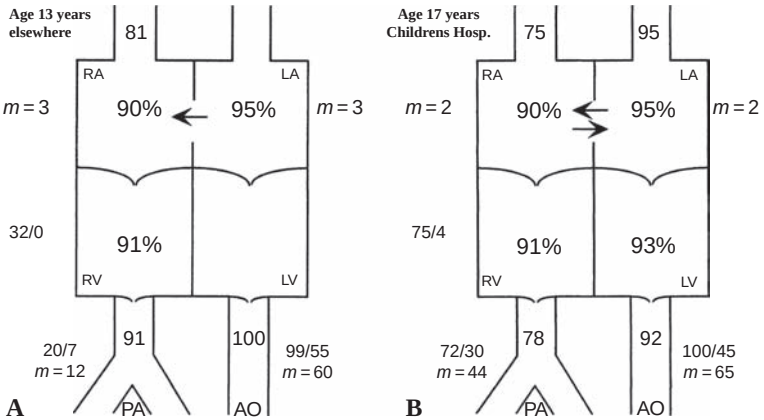

FIGURE 29.2 Catheterization data derived from two studies of the same female patient. The data obtained at age 13 (A) were interpreted as compatible with a small atrial septal defect of insufficient size to require closure. Some years later, she had developed pulmonary vascular obstructive disease (B) and was no longer shunting enough to recommend surgery. Death occurred 5 years later. AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; numeric values within the schematic, oxygen saturation (%); numeric values outside the schematic, pressure (mm Hg). Adapted from Fyler DC, ed. *Nadas Pediatric Cardiology*. Philadelphia, PA: Hanley & Belfus; 1992.

especially if views obtained with echocardiography are not diagnostic. MRI is also excellent at determining the location of the pulmonary veins as well as calculating ventricular volumes and shunt fraction.

VI. TREATMENT. Medical intervention is typically not required preoperatively, because many patients are asymptomatic. Congestive symptoms may be improved with standard diuretic therapy. Rhythm disturbances such as atrial fibrillation require attention with respect to rate control and anticoagulation. Endocarditis antibiotic prophylaxis during dental procedures is not required in the setting of an isolated ASD before surgery, but it is warranted for 6 months after surgical or device closure (AHA/ACC class IIa).

A. Surgical or transcatheter therapy. The mainstay of therapy is closure of the defect by surgical or transcatheter techniques. Because of the reduced life expectancy associated with an unrepaired ASD, closure is recommended at diagnosis if there is evidence of a hemodynamically significant shunt ($Q_p/Q_s \geq 1.5{:}1$), evidence of right heart dilation, and evidence of probable paradoxical embolism or associated symptoms. In the setting of pulmonary hypertension, pulmonary reactivity to vasodilators should be documented and a net left-to-right shunt demonstrated during catheterization before consideration for closure. Alternatively, the defect can be temporarily balloon occluded at the time of catheterization, and the hemodynamic effects are directly measured. Situations in which ASD closure should not be pursued are listed in Table 29.1 and include advanced pulmonary hypertension (Eisenmenger syndrome) and severe LV dysfunction with elevated LA pressure.

B. Primary surgical closure has been the standard approach for many years. Generally, surgical closure is the treatment of choice for ostium primum and sinus venosus defects. Patients with secundum ASDs and anatomy that is not amenable to percutaneous closure (ASD diameter > 35 mm; inadequate septal rims to permit device deployment; or close proximity to AV valves, coronary sinus, or venae cavae) are

TABLE 29.1 Conditions Where Atrial Septal Defect Closure Is Not Favored

Defect is too small to be hemodynamically significant
Pulmonary hypertension is too advanced
Severe LV dysfunction, where ASD is acting as a "pop-off" valve for the left ventricle
In most cases where ASD is diagnosed in pregnancy, closure can be postponed until 6 months after delivery

ASD, atrial septal defect; LV, left ventricular.

also candidates for open surgical closure. Depending on the defect size and location, the secundum ASD can be closed by primary suture or, if needed, by the use of an autologous pericardial or synthetic patch. Ostium primum defects require patch closure as well as repair of the likely cleft mitral valve. Repair of sinus venosus defects is technically more challenging, as the pulmonary veins often have anomalous drainage and require rerouting.

1. Important preoperative risk factors include older age at operation, presence of atrial fibrillation, and elevated pulmonary pressure and resistance.
2. Postoperatively, patients are at risk for heart block, which is a significant complication in these cases. They are also at risk for postpericardiotomy syndrome, more so than after other surgery for congenital defects. Atrial arrhythmias may persist in short-term and long-term follow-ups because the RA and RV sizes may take time to return to normal, so anticoagulation is often recommended for several months after surgery. In some centers, prophylactic β-adrenergic blockade is advocated empirically for 3 to 6 months after surgery.

C. Transcatheter closure of a secundum ASD has become an attractive alternative to surgical closure and is now considered the treatment of choice. Any patient with an isolated secundum ASD may be suitable for transcatheter closure, which is generally assisted with TEE or intracardiac echocardiography in addition to fluoroscopy. Catheter closure decreases hospital length of stay, avoids surgical wounds and their possible complications, and significantly speeds up postprocedure recovery. With the devices available today, defects with a resting diameter of < 35 mm may be considered. In general, the gently stretched diameter of the defect is approximately 6 to 8 mm greater than the resting diameter. The defect must be located centrally with adequate room for the device to be positioned, without interference of other intracardiac structures such as the AV valves, coronary sinus, or pulmonary veins. The US Food and Drug Administration (FDA) has approved two devices for the closure of secundum ASDs: the Amplatzer Septal Occluder (AGA Medical Corporation, Golden Valley, MN) approved in December 2001 and the Helex Septal Occluder (WL Gore & Associates, Flagstaff, AZ) approved in August 2006. Studies have proved the safety and efficacy of catheter-based closure of a secundum ASD compared with surgical closure. The Amplatzer device consists of two disks made of Nitinol wire mesh filled with polyester fabric and separated by a narrower waist, which is appropriately fitted by balloon sizing. It is inserted percutaneously through a 6F to 12F sheath, depending on the device size required. The Helex device is also disklike and consists of expanded polytetrafluoroethylene (ePTFE) patch material supported by a single Nitinol wire frame. Major complications, such as cardiac perforation or device embolization, occur very rarely (generally fewer than 1% of cases), and successful closure of the defect is achieved in up to 95% of all patients. After closure, antiplatelet therapy, frequently aspirin and clopidogrel, is prescribed for a minimum of 6 months, after which time the device is generally believed to have endothelialized.

VII. PROGNOSIS. Hemodynamically significant ASDs are associated with increased morbidity and mortality. Long-term outcomes can be improved by closing these defects, especially if performed early in life. Atrial arrhythmias are common, especially in older patients, and are the result of long-standing atrial stretch. Arrhythmias, particularly atrial flutter and fibrillation, contribute to a significant portion of the morbidity and mortality of older patients, particularly the risk of systemic embolization and the resultant stroke. It has been demonstrated that age at the time of surgical repair is inversely related to the risk of subsequent atrial fibrillation or flutter after repair and argues for earlier closure. Some have advocated for consideration of a concomitant ablation procedure in high-risk patients, but the available data do not generally support this.

The functional capacity of patients frequently improves after closure of the ASD, and often they do not realize how severely their functional capacity had been affected until after the defect is closed. In addition, improvements in LV filling and systemic cardiac output are seen rapidly after defect closure. Reduced RA and RV volumes can be seen within 24 hours and continue to improve over the course of the first year following closure.

PFO AND ATRIAL SEPTAL ANEURYSM

I. PATHOPHYSIOLOGY. PFO can result in transient right-to-left shunting of blood flow, usually when RA pressure exceeds LA pressure such as during coughing or straining. These defects generally do not cause significant hemodynamic derangements. The clinical importance of an atrial septal aneurysm or a PFO is its impact on the risk of stroke. PFO features that increase the risk of a paradoxical embolus include large tunnel lengths (≥ 4 mm), high mobility of the valve of the foramen ovale, a well-formed eustachian valve, and a resting right-to-left shunt.

II. CLINICAL MANIFESTATIONS. Generally these defects are asymptomatic, most often coming to attention in patients with cryptogenic (unexplained) stroke. PFO is more common in patients with cryptogenic stroke than in the general population, but PFO alone has not been shown to be an independent risk factor for cryptogenic stroke. There are now accumulating data to suggest that an isolated PFO is not associated with an increased risk of recurrent ischemic stroke. The data in patients with both a PFO and an ASD are conflicting but suggest increased risk of recurrent stroke when both lesions are present. PFO should be suspected in young patients who sustain a stroke, as more than one-half of stroke patients younger than 45 years have a PFO. Other less common clinical associations with PFO include migraine headaches, platypnea–orthodeoxia syndrome, and decompression illness in divers and those who work in high altitudes.

III. DIAGNOSTIC STUDIES. **Echocardiography** can easily differentiate between an ASD and a PFO if the interatrial septum is well visualized. If this is not possible via a transthoracic approach, a TEE may be necessary. A simple way to determine if a shunt is present is the "**bubble study**," which is the injection of agitated saline via an upper extremity vein. If shunting is not present at rest, the patient can perform a Valsalva maneuver, which augments right-to-left shunt. If bubbles can be seen in the left atrium or the left ventricle within three cardiac cycles on TTE, the diagnosis of an interatrial right-to-left shunt is established. Generally, administration of agitated saline in patients with suspected right-to-left shunts is considered safe, but there have been rare case reports of cerebral ischemic events from passage of bubbles into the systemic circulation.

TEE will likely be required in most adults for better visualization of the interatrial septum. TEE helps to differentiate between a PFO and a secundum ASD, both of which can have positive bubble studies. TEE also allows assessment of other potential sources of emboli, such as atheroma in the aortic arch, thrombus in the LA appendage, or cardiac tumors.

TABLE 29.2 Contraindications to Percutaneous Patent Foramen Ovale Closure

Presence of an alternative source of emboli
Severe pulmonary hypertension
Recent gastrointestinal bleeding
Presence of congenital heart defect that needs surgical repair
Documented hypercoaguable state
Hypersensitivity or contraindication to antiplatelet or anticoagulant therapy
Unexplained fever or infection

IV. TREATMENT. Unfortunately, there is no clear consensus on primary or secondary prevention measures for patients found to have a PFO or atrial septal aneurysm. In general, atrial septal abnormalities are not treated for primary prevention of stroke. Regarding secondary prevention, most patients with neurologic events are treated with antiplatelet agents (either aspirin or a thienopyridine, or both), anticoagulants (warfarin), and percutaneous or surgical closure, although no clear consensus exists and the only randomized controlled study reporting results to date failed to demonstrate a benefit of closure over medical therapy. The CLOSURE I trial (reported at AHA 2010) examined the role of PFO closure for first time stroke/TIA and found no difference in the composite primary end point of stroke or TIA at 2 years, all-cause 30-day mortality, and neurologic mortality between 31 days and 2 years, with closure compared with aspirin, warfarin, or both. There are several other ongoing trials that are comparing percutaneous PFO closure with medical therapy. These include the CLOSE trial, the PC-Trial, the RESPECT trial, and the REDUCE trial. In general, device closure should be mainly performed in patients with recurrent cryptogenic stroke despite aggressive medical therapy. The same devices utilized for ASD closure are generally used to percutaneously close PFO. Contraindications to percutaneous closure are noted in Table 29.2.

Primary surgical closure of PFO is generally not pursued, unless the patient needs concomitant surgery for other conditions. Indiscriminant repair of PFO incidentally found at surgery may actually increase short-term stroke risk and should therefore be avoided.

There is a dearth of data to support PFO closure in patients with migraine headaches. The MIST (Migraine Intervention with STARFlex Technology) trial randomized 147 participants with severe migraine headaches and right-to-left shunt consistent with PFO to either percutaneous closure or sham procedure. After 6 months, there was no statistically significant difference in the primary end point of complete cessation of migraine headache or in a host of secondary end points including change in severity, quality, and frequency of headache as well as quality of life. As such, device closure should only be performed in migraine patients who are part of a randomized clinical study.

Patients with platypnea–orthodeoxia syndrome (acute arterial desaturation with change in position from supine to upright) should be considered for closure, as oxygen saturation generally improves with successful elimination of the right-to-left shunt.

CHAPTER 30

Christopher H. May

Ventricular Septal Defect

I. Introduction

A. Ventricular septal defect (VSD) is one of the most common congenital heart defects in both children and adults. The prevalence in neonates has been reported to be as high as 5% when screened with color Doppler echocardiography, although most of these are miniscule defects that close spontaneously within the first year. Thus the true prevalence is difficult to ascertain, given that many defects close spontaneously

and patients are frequently asymptomatic with smaller lesions. VSDs are frequently associated with other congenital defects, particularly infundibular stenosis or valvar pulmonary stenosis. Isolated VSDs account for about 20% to 25% of all congenital heart defects in childhood. Unlike many other congenital abnormalities, males and females appear to be affected equally.

B. Isolated VSDs are found in approximately 10% of adult patients with congenital heart disease. This reflects the natural tendency for spontaneous closure during infancy and an improved ability to confirm the diagnosis in childhood, which leads to surgical closure.

C. Natural history

1. **Spontaneous closure** occurs most commonly with smaller, restrictive VSDs, usually before the age of 2 years. In general, nearly 35% of perimembranous defects close spontaneously and 75% to 80% of all small VSDs close spontaneously by 10 years of age. These higher rates of spontaneous closure in more recent series are a reflection of the ability to diagnose much smaller defects with more contemporary echocardiographic modalities. Large and nonrestrictive defects have significantly lower spontaneous closure rates (approximately 10% to 15%); malalignment defects rarely close spontaneously. Defects close by two mechanisms: (1) by muscular septum growth and (2) by "aneurysmal tissue" from a septal leaflet of the tricuspid valve as in the case of perimembranous defects. For VSDs that persist, a restrictive nature can protect the patient from pulmonary vascular injury given the flow-limiting nature of these defects.
2. **Endocarditis** is a risk because of the presence of a high-velocity, turbulent jet into the right ventricle. Endocarditis most frequently involves the septal leaflet of the tricuspid valve apparatus at the point of jet impact. The risk of endocarditis is roughly 4% to 10% for the first 30 years of life. Muscular VSDs have a lower incidence of endocarditis, as the jet is attenuated prior to reaching the tricuspid valve.
3. A large VSD during childhood is typically associated with significant **left-to-right shunt** and eventual development of congestive heart failure. Children with very large defects usually present during infancy or early childhood with signs and symptoms of heart failure and pulmonary hypertension. Patients with moderate-sized VSDs can survive to adulthood before detection. Given the gradual development of symptoms in these patients, they may not present until late in the disease course. In these patients, the excess right-sided flow may lead to pulmonary vascular disease and Eisenmenger physiology if left untreated. As pulmonary vascular resistance increases, the left-to-right shunt changes to a right-to-left flow. The VSD murmur disappears during this transition and is often replaced by the murmur of tricuspid regurgitation. After Eisenmenger physiology has developed, patients rarely survive beyond the fourth decade. Complications in patients with Eisenmenger syndrome include pulmonary hemorrhage, endocarditis, cerebral abscess (from hypoxemia), ventricular arrhythmias, and the complications associated with erythrocytosis. Poor prognostic factors in this population include syncope, congestive failure, and hemoptysis.
4. Risk factors for decreased survival include cardiomegaly seen on the chest radiograph; elevated pulmonary artery systolic pressure (> 60 mm Hg and/or more than one-half of the systemic pressure); cardiovascular symptoms such as shortness of breath, fatigue, or dyspnea on exertion; and progressive aortic insufficiency. Good prognostic factors include normal left ventricular (LV) size and function, small left-to-right shunt, normal pulmonary pressures or resistance, an intact vasodilator response in the pulmonary vasculature, and a lack of symptoms.
5. Genetic factors play a significant role in this disease, as in other forms of congenital heart disease. Having an affected father increases the risk of VSD in

the offspring to 2%; moreover, an affected mother appears to confer an even higher risk of recurrence in offspring—as high as 6% to 10%. In general, VSDs arise due to a combination of polygenic, multifactorial abnormalities. However, several monogenetic abnormalities leading to VSDs such as mutations in the transcription factors TBX5 and GATA4 have recently been described.

II. ANATOMY

A. Embryology. Partitioning of the ventricular mass begins as a muscular ridge in the floor of the ventricle near the apex. This ridge later undergoes active growth, which forms the muscular ventricular septum. Concomitantly, the endocardial cushions fuse and the two regions meet, completing closure of the interventricular foramen. Figure 30.1 shows anatomic localization of VSDs.

B. Defect size. The consequences of a VSD depend on the size of the defect and the pulmonary and systemic vascular resistances. Smaller defects provide higher resistance to flow and will have little impact on right-sided flow. **The VSD is** described as **small** when the defect size is **less than one-third of the size of the aortic root, moderate** when the defect size is **less than one-half of the size of the aortic root,** and **large** when the defect size is equal to or **larger than the size of the aortic root.** However, other indirect measures, including clinical signs and symptoms and echocardiographic features, must be taken into consideration when determining the size and clinical significance of a VSD. VSD size is often classified on the basis of its hemodynamic consequences:

1. **Restrictive** VSDs result in a significant pressure gradient between the left and right ventricles (e.g., pulmonary/aortic systolic pressure ratio < 0.3) and are associated with a small shunt ($Q_p/Q_s \leq 1.4{:}1$).
2. **Moderately restrictive** VSDs produce an intermediate interventricular gradient and result in a moderate shunt ($Q_p/Q_s = 1.4$ to $2.2{:}1$).
3. **Nonrestrictive** VSDs are usually larger than 1 cm^2 and are associated with a large shunt ($Q_p/Q_s > 2.2{:}1$). The pressures in the left ventricle and right ventricle will eventually approach equalization, and the amount of flow across the defect will be determined by the ratio of pulmonary-to-systemic vascular resistance.

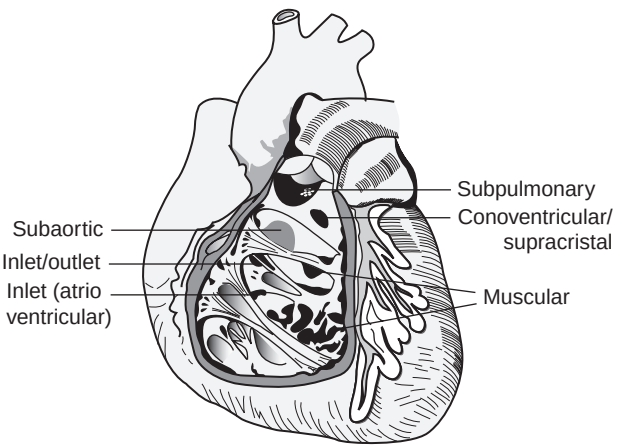

FIGURE 30.1 Anatomic localization of ventricular septal defects.

C. VSD types

1. **Membranous** defects are the most common type, accounting for approximately **70% to 80% of VSDs**. The membranous septum is the area under the aortic valve on the left side and next to the septal leaflet of the tricuspid valve on the right side. Most of these defects extend into the infundibular region and are then referred to as perimembranous. **Membranous defects** are less likely to be associated with additional intracardiac defects and **have a high rate of spontaneous closure**. However, when there is malalignment of the defect, spontaneous closure is unlikely.
2. **Muscular** defects account for approximately 5% to 20% of VSDs and can be single or multiple (i.e., Swiss cheese septum). These defects, when single, also have a high spontaneous closure rate.
3. **Inlet or atrioventricular (AV) canal–type** defects account for approximately 5% to 8% of cases. These defects rarely close spontaneously, are usually large, and are associated with abnormalities of the AV valves. These abnormalities range from cleft mitral and tricuspid valves to the common AV valve, as seen in complete AV canal defect. This type of defect in the inlet ventricular septum is commonly seen in patients with Down syndrome (Trisomy 21).
4. **Supracristal or subaortic** defects account for approximately 5% to 7% of cases and are located immediately beneath the pulmonary and aortic valves. These defects vary in size but are often small. Because of their **proximity to the aortic valve, aortic leaflet tissue can invaginate and result in their closure, with the unfortunate result of significant aortic regurgitation**.

D. Associated lesions. Approximately 20% of VSDs are associated with many other forms of congenital heart disease, including aortic coarctation, bicuspid aortic valve, and patent ductus arteriosus. Of patients who present with a VSD, 5% to 10% will develop aortic regurgitation because of poor support of the right coronary cusp and the Venturi effect caused by the VSD jet, resulting in prolapse of one of the aortic valve leaflets. Discrete, fibrous subaortic stenosis and right ventricular (RV) outflow tract obstruction are less common associations. Less than 10% develop subvalvular pulmonary stenosis or an obstructive muscle bundle referred to as a double-chamber right ventricle. VSD is also associated with transposition of the great arteries, tetralogy of Fallot, and Trisomies 13, 18, and 21.

III. CLINICAL PRESENTATION.

Adult presentation occurs most frequently in small, restrictive VSDs and occasionally occurs in patients with moderate lesions and associated pulmonary hypertension or with Eisenmenger syndrome in large, unoperated lesions.

A. Symptoms. The most common symptoms in adult patients with hemodynamically significant VSD are dyspnea on exertion and exercise intolerance. The symptoms are related to the degree and chronicity of left-to-right shunt and the resultant increase in pulmonary pressure and resistance.

B. Physical findings. The auscultatory findings classically include a holosystolic murmur of varying intensity. Smaller muscular defects may produce a high-frequency early systolic murmur that ends before the second heart sound (S_2) because of closure from muscular contraction of the septum. The pitch of the murmur can be a clue to the size and nature of the defect. Smaller and more restrictive defects produce higher pitched and louder murmurs that may be associated with a palpable thrill. Another important feature is the intensity of the pulmonary component of S_2, which if increased suggests increased pulmonary pressure. An RV heave may be appreciated in patients with RV volume overload. A diastolic flow rumble at the apex may be heard in large left-to-right shunts due to increased flow across an otherwise normal mitral valve. Depending on associated lesions, other findings may be present such as a diastolic murmur of aortic insufficiency that may occur with

subaortic defects. A prominent systolic ejection murmur at the left upper sternal border suggests subvalvular pulmonic stenosis or double-chamber right ventricle. As pulmonary hypertension and right-to-left shunting develop, other signs including cyanosis, elevated jugular venous pressure, enlarged and pulsatile liver, clubbing, and a decrease in murmur intensity may occur. A systolic murmur in this setting often reflects concomitant tricuspid insufficiency. Notably, the murmur of a large VSD is often less harsh and more blowing in nature than that of a small VSD because of the absence of a significant pressure gradient across the larger defect which results in less turbulent flow.

C. The **differential diagnosis** on examination includes tricuspid regurgitation, acyanotic tetralogy of Fallot with a pulmonary outflow murmur, isolated subvalvular pulmonic stenosis, and hypertrophic cardiomyopathy.

IV. LABORATORY TESTS

A. The **electrocardiogram (ECG)** may be unremarkable with small defects or reveal left atrial and LV enlargement in patients with larger defects. An inlet or AV canal defect can be diagnosed from the ECG based on the presence of marked left-axis deviation. Right-axis deviation suggests elevated RV and pulmonary artery pressure. After surgical repair, right bundle branch block may occur.

B. A **chest radiograph** is often helpful in determining the degree of left-to-right shunt. A small-sized or normal-sized heart with normal pulmonary vascular markings on the chest radiograph suggests a hemodynamically insignificant lesion, whereas cardiomegaly and left atrial and LV enlargement are seen with large left-to-right shunts. A large defect associated with a small heart and oligemic lung fields should raise the suspicion of pulmonary vascular disease.

V. DIAGNOSTIC TESTING

A. **Echocardiography** is the diagnostic modality of choice for VSDs and associated lesions. Transthoracic echocardiographic imaging is almost always sufficient in the child and young adult, but transesophageal echocardiographic imaging may be required in some older adult patients. Defect size and location should be defined using two-dimensional and color Doppler techniques. Complete scans of the ventricular septum should be made to rule out additional defects. Optimal images are usually obtained from the parasternal long-axis and short-axis views and the apical four-chamber view; other views may fail to visualize the VSD jet, owing to perpendicular alignment of the echocardiographic probe and the jet. In the younger patient, subcostal coronal and sagittal views may also be helpful. Measurements of left atrial and LV size are key to determining the amount of volume load and magnitude of the left-to-right shunt. Echocardiographic features of pulmonary hypertension are helpful in confirming the impending reversal of shunt. Quantification of shunt velocity provides an estimate of the restrictive nature of the defect. Higher velocities indicate a more restrictive defect, reducing the likelihood that the patient has experienced pulmonary vascular insult. Systemic blood pressure should be noted when the velocity across the VSD is measured. Assuming no LV outflow obstruction, RV pressure can then be estimated based on the gradient across the VSD. This pressure can also be estimated if tricuspid insufficiency exists. A **perimembranous VSD** can be associated with a **ventricular septal aneurysm formed by the septal leaflet of the tricuspid valve bowing into the defect**. Similarly, supracristal VSDs are associated with aortic insufficiency caused by prolapse of the right or left coronary cusps into the VSD. A complete evaluation is always indicated to exclude other associated findings such as aortic coarctation, atrial septal defect, patent ductus arteriosus, and RV or LV outflow tract obstruction.

B. Catheterization is seldom needed in the management of isolated VSD in the infant or child. Surgical correction, when indicated, proceeds in most cases based on echocardiographic evaluation. In the adult, catheterization should be considered if anatomic questions remain despite transthoracic and transesophageal echocardiography or if pulmonary hypertension is suspected based on these studies. Hemodynamic assessment should include quantification of cardiac index and careful oximetric definition of the shunt level and quantity. A step-up in saturation measured at the pulmonary artery level confirms persistent left-to-right shunt across the defect and should correlate with acceptable pulmonary artery pressures and resistance. Evidence of low pulmonary artery saturations is expected with elevations of pulmonary resistance. Simultaneous comparison of RV pressure with systemic pressure is mandatory in these cases, along with the documentation of changes in response to oxygen or nitric oxide administration. Left ventriculography performed with **left anterior–oblique and cranial angulation** demonstrates the defect in most cases. If an inlet-type defect is present, the hepatoclavicular view (about 40° left anterior–oblique and 40° cranial) is usually adequate. Right ventriculography does not adequately opacify the left ventricle unless there is suprasystemic RV pressure. Coronary angiography should be performed when patients are felt to be at risk for coronary artery disease and likely to require operative intervention. Aortography can be helpful in eliminating the possibility of an associated ductus arteriosus or coarctation of the aorta.

C. Cardiac **computed tomography** (CT) can be used to assess VSD anatomy in patients with suboptimal echocardiographic images, but unlike magnetic resonance imaging (MRI), CT does not provide added information about shunt fraction (see Chapter 52) and carries additional risk associated with radiation and intravenous contrast administration.

D. MRI, using spin–echo and velocity-encoded cine sequences, can also be used to delineate VSD location and shunt fraction. MRI is particularly helpful in patients with associated complex lesions and those with inadequate echocardiographic images (see Chapter 51).

VI. THERAPY. Factors supporting intervention include cardiomegaly on the chest radiograph, significant left-to-right shunt (pulmonary-to-systemic flow ratios > 1.5:1), elevated but responsive pulmonary vascular resistance, symptoms of congestive failure or associated lesions such as aortic insufficiency, RV or LV outflow tract obstruction, and recurrent endocarditis. Management of VSD after myocardial infarction is discussed separately in Chapter 3.

A. Medical management in symptomatic cases without Eisenmenger physiology involves anticongestive measures such as the use of diuretics and digoxin. Efforts should then be focused on addressing suitability for surgical closure. Endocarditis is a recognized complication of VSD. In the patient with culture-proven endocarditis, 4 to 6 weeks of antibiotics should be administered parenterally before consideration of intervention. This must be tailored to the individual patient's clinical status and the infective organism's identification and sensitivity as well as the presence of concomitant valvular lesions and prosthetic material. For patients who have developed elevated pulmonary vascular resistance, selective pulmonary vasodilators, including phosphodiesterase-5 inhibitors, prostacyclin analogs, and endothelin receptor antagonists, may improve hemodynamics and exercise tolerance (see Chapter 32).

B. Transcatheter device closure of VSDs is being performed on an investigational or compassionate-use basis in selected medical centers. The Amplatzer Muscular VSD Occluder is FDA approved and can technically close many muscular defects. Perimembranous defects, however, pose particular problems for transcatheter closure given their close proximity to the conduction system and the AV and semilunar valves, although recent data from the investigational Amplatzer Membraneous

VSD Occluder are promising. Although long-term data from these devices are lacking, recent studies show that the rate of complete closure for the Amplatzer membranous device at 6 months is 96% and is 100% for the muscular occluder at 3 to 96 months follow-up. Complications with these devices include early or late-onset complete heart block, arrhythmia, tricuspid valve damage resulting in stenosis or regurgitation, and mechanical device failure during deployment. Transcatheter closure of VSDs after ventricular septal rupture in the setting of myocardial infarction has also been performed in selected individuals who are considered high-risk surgical candidates. Surgery, however, is still the preferred treatment modality in this setting.

C. **Surgical closure** continues to be the primary means of defect repair. Outcomes after VSD closure are good in children, with low mortality rates of 2% to 3%. Repair of VSDs in patients with evidence of increased pulmonary artery pressure is generally performed before the age of 2 years and, in many centers, in the first year of life. Surgical closure in the symptomatic adult appears to be well tolerated, with acceptable mortality and improved functional status. Irreversible pulmonary vascular disease with Eisenmenger physiology, however, is a general contraindication for surgical closure because right heart failure will often develop thereafter. Pulmonary artery banding (performed to limit pulmonary blood flow) was more frequently done in the past and is now reserved for the few patients who are very small, have lung disease, or who have complex, multiple VSDs. Postoperative sequelae include residual patch leaks, as well as supraventricular and ventricular arrhythmias. More recent studies have shown the presence of a residual shunt following surgical closure in 5% to 31% of patients depending on the type of VSD that was repaired. Recent data suggest that postsurgical residual VSDs < 2 mm close spontaneously within 1 year in the majority (83%) of patients.

D. In children for whom transcatheter and surgical approaches are technically difficult or particularly high risk, a **hybrid approach** has been explored. In these patients, a sternotomy is performed, and the device is placed through the anterior wall of the right ventricle under fluoroscopic and echocardiographic guidance.

E. According to the American Heart Association (AHA) guidelines, **antibiotic prophylaxis** is recommended in three situations in relation to congenital heart disease: (1) unrepaired cyanotic defect (i.e., VSD with right-to-left shunt), (2) repaired defect (i.e., VSD) with prosthetic material/device for the first 6 months, and (3) repaired defect (i.e., VSD) with residual defect at the site of a prosthetic patch/device. In addition, excellent oral hygiene and regular dental examinations are an important component in reducing the risk of developing infective endocarditis.

F. **Eisenmenger syndrome** is usually referred to in the context of ***irreversible pulmonary hypertension from long-standing exposure of the pulmonary vasculature to left-to-right shunting*** across a VSD. However, this physiology can occur as a result of any left-to-right shunt, including patent ductus arteriosus and, less commonly, isolated atrial septal defect. As a result of the elevated pulmonary pressures, the direction of shunting is reversed across the defect, producing systemic cyanosis and its associated complications. As described above, newer agents aimed at decreasing resistance in the pulmonary vasculature may be beneficial in these patients. **Pregnancy is poorly tolerated and is contraindicated in the presence of Eisenmenger syndrome** (see Chapter 38).

G. Long-term follow-up is required in patients whose VSDs were repaired later in life, since the majority of patients already have some degree of pulmonary hypertension, LV dysfunction, or both. Patients with residual shunt after repair, arrhythmias, or conduction blocks also require continued follow-up.

ACKNOWLEDGMENTS: *The author thanks Drs. J. Donald Moore, Matthew Hook, and Samuel Unzek for their contributions to earlier editions of this chapter.*

Patent Ductus Arteriosus and Coarctation of the Aorta

I. PATENT DUCTUS ARTERIOSUS—INTRODUCTION

A. The ductus arteriosus is a fetal communication between the descending aorta just distal to the left subclavian artery and the main pulmonary artery near its bifurcation. A patent ductus arteriosus (PDA) occurs when the ductus arteriosus fails to close and regress after birth to form the ligamentum arteriosum. PDA occurs in approximately 1 of 2,000 live births, but it is relatively uncommon among the adult population. In infants, it accounts for 10% to 12% of all congenital heart disease.

B. Natural history. The natural history depends on the size of the PDA, the direction of the shunt, and the development of any associated complications. At birth, 95% of patients with isolated PDA have left-to-right shunts and normal, or near-normal, pulmonary pressures. Patients with normal pulmonary artery pressures and no evidence of chronic left ventricular volume overload have a better prognosis. If untreated, life expectancy of patients with PDA is shortened; one-third of patients with PDA die by the age of 40 and almost two-thirds die by the age of 60. With a PDA, **congestive heart failure (CHF) can occur** because of chronic left heart volume overload. In patients with death related to PDA, CHF is the most common cause. Development of right-to-left shunting is also an ominous sign because it reflects the development of advanced pulmonary vascular disease and associated elevation in right-sided cardiac pressures (see Chapter 32 for discussion on Eisenmenger's syndrome).

C. Risk factors. Factors that increase risk for PDA include maternal rubella infection, birth at high altitude, premature birth, female sex, and genetic factors. In infants born at < 28 weeks of gestation, there is a 60% incidence of PDA. PDAs are twice as common in female infants as in male infants and in some instances have a genetic component. In a family in which one child has a PDA, there is approximately a 3% risk of having a PDA in subsequent offspring.

II. ANATOMY AND PATHOPHYSIOLOGY

A. Embryology. The ductus arteriosus is a **normal and essential component** of cardiovascular development that originates from the distal sixth left aortic arch. A PDA is most commonly funnel shaped with the larger aortic end (ampulla) distal to the left subclavian artery, then narrowing toward the pulmonary end, with insertion at the junction of the main and left pulmonary arteries. The Krichenko classification system describes the angiographic appearance of PDA (Table 31.1). In right-sided aortic arch, the anatomy of PDA can vary significantly: the PDA can arise from the left innominate artery and insert into the proximal left pulmonary artery or arise distal to the right subclavian artery with insertion into the proximal right pulmonary artery. Bilateral PDAs can also occur.

B. Fetal circulation. The presence of the ductus arteriosus in the fetal circulation is essential to allow **right-to-left shunting of nutrient-rich, oxygenated blood**

TABLE 31.1 Krichenko Classification of Patent Ductus Arteriosus Appearance on Angiography

Type A	Conical	Well-defined aortic ampulla and constriction near pulmonary insertion
Type B	Window	Short, with narrowing near aortic insertion
Type C	Tubular	Tubular duct without constrictions
Type D	Complex	Multiple constrictions
Type E	Elongated	Long PDA with conical appearance and multiple constrictions

PDA, patent ductus arteriosus.

from the placenta to the fetal systemic circulation, thereby bypassing the fetal pulmonary circuit. In the normal fetal circulation, oxygenated blood travels from the mother through the placenta to the fetus. The oxygen-rich blood traverses the fetal inferior vena cava, right atrium, right ventricle, and main pulmonary artery. The fetal pulmonary arteries are constricted and have high pulmonary vascular resistance. Oxygenated blood bypasses the fetal pulmonary circulation and enters through the ductus arteriosus to the lower resistance systemic circulation. Oxygenated blood then enters the fetal aorta distal to the left subclavian artery, perfuses the fetal systemic circulation, becomes deoxygenated, and returns to the maternal circulation. **In the fetus, the ductus arteriosus is kept open by low arterial oxygen content and placental prostaglandin E2 (PGE2).**

C. Birth. Several **changes occur at birth** to initiate normal functional **closure of the ductus arteriosus within the first 15 to 18 hours of life.** Spontaneous respirations result in increased blood oxygen content. Prostaglandin levels decrease because of placental ligation and increased metabolism of prostaglandins within the pulmonary circulation by prostaglandin dehydrogenase. The combination of increased oxygen content and lowered circulating prostaglandin levels usually results in closure of the ductus arteriosus. Generally, the ductus arteriosus is hemodynamically insignificant within 15 hours and completely closed by 2 to 3 weeks. The **fibrotic remnant** of this structure persists in the adult as the **ligamentum arteriosum. Spontaneous closure of a PDA is unlikely in term infants after 3 months and in preterm infants after 12 months.**

III. CLINICAL PRESENTATION

A. Symptoms. Severity of symptoms depends on the degree of left-to-right shunting; and it is determined by the size of the PDA, ductal resistance, cardiac output, as well as the systemic and pulmonary vascular resistances. PDA size is categorized by the degree of left-to-right shunting determined by the pulmonary-to-systemic flow ratio: Q_p:Q_s (Table 31.2). Between 25% and 40% of patients with PDA are asymptomatic, especially those with a small PDA. They are often diagnosed by auscultation

TABLE 31.2 Patent Ductus Arteriosus Size by Q_p:Q_s

Q_p:Q_s	Size
< 1.5	Small
1.5–2.2	Moderate
> 2.2	Large

of a continuous murmur on examination or incidentally during diagnostic testing. With larger PDAs, symptoms may develop. The most common symptom is exercise intolerance followed by dyspnea, peripheral edema, and palpitations. As is often the case in adult congenital heart disease, a previously well-tolerated PDA may become manifest in the setting of acquired heart disease such as ischemia, essential hypertension, and valvular disease.

B. Physical examination. Patients with PDAs may present with a wide range of physical findings. Pulse pressure may be wide because of diastolic runoff into the PDA, and peripheral pulses may be bounding. The jugular venous pressure is often normal with a small PDA, whereas with a large PDA, prominent *a* and *v* waves may be present. Precordial palpation often reveals a normal precordial impulse with a small PDA and a prominent left ventricular impulse with a large PDA. A **harsh, continuous murmur may be heard at the left first or second intercostal space**. The murmur envelops the second heart sound (S_2) and decreases in intensity during diastole. A small PDA has a soft, high-frequency, continuous murmur, whereas a large PDA classically has a machinerylike, loud murmur. With a large PDA, a middiastolic apical murmur may occur because of increased diastolic flow across the mitral valve. If **pulmonary hypertension** is present, a right ventricular lift may be present and the pulmonic component of S_2 will have increased intensity. The duration of the diastolic murmur reflects pulmonary artery pressures; elevated pulmonary artery pressures lead to a decreased gradient for left-to-right flow through the PDA during diastole, which results in a shorter diastolic murmur. As pulmonary pressure increases, the systolic component of the murmur shortens. Right-to-left flow may not generate a systolic murmur. For patients with a right-to-left shunt, a pathognomonic physical finding is **differential cyanosis of the lower extremities and left hand**.

C. Complications. The most common complications of PDA include **CHF, infective endocarditis**, and **pulmonary hypertension**. CHF occurs through volume overload of the left side of the heart and may be accompanied by **atrial fibrillation**. Vegetations generally develop on the pulmonary side of the PDA, and septic lung emboli may occur. Untreated PDAs with audible murmurs have a risk of infective endocarditis of 0.45%/y after the second decade. Spontaneously occurring **aneurysms of the ductus arteriosus** have been reported, although they are typically seen in association with endarteritis or among very young or very old patients. Pulmonary hypertension develops as a result of increased pulmonary vascular flow from a large PDA with significant left-to-right flow. Elevation in right-sided pressures may eventually result in Eisenmenger's physiology, right-to-left flow, and isolated cyanosis and clubbing of lower extremities (occurring in 5% of unrepaired PDA patients) with signs of pulmonary hypertension.

D. Differential diagnosis. The differential diagnosis of PDA includes ventricular septal defect associated with aortic insufficiency, aortopulmonary window, pulmonary atresia with systemic collateral vessels, innocent venous hum, and arteriovenous communications such as pulmonary arteriovenous fistula, coronary artery fistula, systemic arteriovenous fistula, and ruptured sinus of Valsalva aneurysm.

IV. LABORATORY TESTING

A. Hematology. Blood laboratory results are generally unremarkable, although compensatory erythrocytosis may be present in the setting of long-standing cyanosis resulting from a right-to-left shunt.

B. Electrocardiogram (ECG). ECG is neither sensitive nor specific for PDA. The ECG for a patient with a small PDA is often normal. Depending on the duration and hemodynamic significance of the PDA, electrocardiographic criteria for left atrial enlargement or left ventricular hypertrophy may be present. If pulmonary hypertension exists, the ECG may demonstrate right ventricular hypertrophy or right atrial enlargement.

C. Chest radiography (CXR). CXR is neither sensitive nor specific for PDA. A normal chest radiograph implies a small, hemodynamically insignificant PDA. With a large PDA, left atrial and left ventricular enlargement may be present, as well as increased pulmonary vascularity. With right-to-left shunting from pulmonary hypertension, the main pulmonary artery is frequently enlarged. The PDA occasionally appears as a separate convexity between the aortic knob and the pulmonary trunk. Calcification of the PDA may be visualized in older individuals.

V. DIAGNOSTIC TESTING. Standard transthoracic echocardiography (TTE) is the preferred initial diagnostic modality because of its low cost and noninvasive nature. Transesophageal echocardiography (TEE) may be required in subjects with suboptimal echocardiographic windows. Cardiac catheterization is typically reserved for therapeutic intervention.

A. TTE has a 42% sensitivity and 100% specificity for the diagnosis of PDA. The suprasternal notch view is usually best for demonstrating the PDA, particularly its aortic origin. The complete course of a PDA may be difficult to follow in some patients because of its tortuosity. Color Doppler imaging can often reveal flow between the descending aorta distal to the left subclavian artery and the pulmonary trunk. It is imperative to demonstrate color Doppler flow within the pulmonary artery, typically on a high parasternal short-axis view. Color Doppler and continuous wave Doppler help determine the direction of flow in the PDA. The timing of flow (systolic or diastolic) depends on pressure gradients between the systemic and pulmonary circulation. Quantitative assessment of shunt velocity is valuable to estimate the degree of restriction across the PDA. This measurement becomes important when planning transcatheter intervention. Diastolic aortic flow reversal is seen in the descending aorta if the shunt is significant. Associated left atrial and left ventricular enlargement also suggest a hemodynamically significant lesion.

B. TEE may be required if TTE windows are suboptimal or nondiagnostic. TTE and TEE have nearly 100% specificity for the diagnosis of PDA, but TEE has a much higher sensitivity (97%) than TTE (42%).

C. Cardiac catheterization is rarely needed for diagnostic purposes. Rarely, PDAs undiagnosed by physical examination or noninvasive testing may be diagnosed during left heart or right heart cardiac catheterization by recognizing the unexpected course of the catheter as it crosses the PDA by measuring a step-up in the oxygen saturation at the level of the left pulmonary artery or by documenting pulmonary opacification by descending aortography.

1. A PDA is best demonstrated by a **descending aortogram** performed in the **lateral projection** with a standard angiographic catheter positioned just below the ductal ampulla. If biplanar imaging is used, the right anterior–oblique cranial projection is sometimes helpful.
2. A PDA can be crossed from the main pulmonary artery or from the descending aorta, with the latter being easier and best guided by the lateral projection. Oximetric sampling typically demonstrates an increase in saturation in the main pulmonary artery compared with the right ventricle. Pulmonary artery and right ventricular pressures may be slightly elevated but typically remain below systemic levels. The etiology is usually pulmonary arterial vascular disease, but it can also be due to pulmonary venous stenosis, mitral stenosis, or left ventricular failure. The presence of systemic pulmonary pressures generally indicates severe and advanced pulmonary vascular disease.

D. Magnetic resonance imaging (MRI) and computed tomography may be useful in defining the anatomy in patients with unusual PDA geometry and in patients with associated abnormalities of the aortic arch.

VI. THERAPY. ACC/AHA 2008 guidelines for adults with congenital heart disease recommend closure of PDA (catheter or surgical) if there is **left atrial or left ventricular**

enlargement or if pulmonary arterial hypertension (PAH) is present with net left-to-right shunt (class I); or of an **asymptomatic small PDA by catheter device** (class IIa). PDA closure is **contraindicated** in patients with **PAH and right-to-left shunt**. Successful closure of PDA generally results in a good prognosis and may prevent adverse left ventricular remodeling resulting from volume overload.

The shape and size of a PDA determine the mode of therapy. Small- or moderate-caliber PDAs are generally closed percutaneously with coils. Large PDAs may require the Amplatzer Duct Occluder (ADO) or surgery. Heavily calcified PDAs represent a relative contraindication to surgical closure because of an increased risk of bleeding and incomplete closure with surgery. Cardiopulmonary bypass may be required for heavily calcified PDAs. PDAs with significant right-to-left shunts and Eisenmenger's physiology should generally not be closed. In patients with pulmonary vascular resistance > 8 U/m^2, lung biopsy has been recommended to determine candidacy for closure. However, even histologically severe pulmonary vascular disease may resolve after closure of the PDA. Reactivity of the pulmonary vascular bed to pulmonary vasodilating agents or significant reduction in pulmonary artery pressure during test occlusion may signal reversibility of pulmonary hypertension, but the absence of these findings does not rule out the possibility of reversibility in the long-term and natural history may be significantly altered by treating with pulmonary vasoactive medications.

A. Since the early 1990s, **transcatheter techniques** have become the **first-line therapy for most PDAs**. Many centers use single or multiple stainless steel coils to achieve complete closure. Numerous devices have been adapted or are under clinical investigation to allow transcatheter closure of larger defects. These procedures can often be performed on an outpatient basis, and complete closure rates at follow-up generally exceed 90% to 95% in most studies. The mortality rate is typically < 1% at experienced centers. Success has been reported even when ductal calcification has been apparent, but large clinical series are lacking.

1. **Percutaneous coil occlusion.** Percutaneous coils were developed in 1992 and are the **preferred treatment for older children and adults with PDAs < 3.5 mm in diameter**. Embolization coils have thrombogenic strands spanning the coils and are placed across the PDA to occlude flow. Advantages include low cost, small-caliber venous access, and easy implantation. Advances include detachable coils and development of a snare-assisted technique, both of which allow assessment and fine-tuning to ensure correct coil position before actual release of the coil. The coils are loaded at the tip of a catheter, the catheter is placed in the PDA under fluoroscopic guidance, and the coils are then deployed. Selected coil sizes are 2 to 2.5 times the narrowest diameter of the PDA. With moderate-sized or large-sized PDAs, multiple coils may be used. However, as PDA size becomes larger (> 3.5 to 4.0 mm), percutaneous, 0.038" coils become a less desired closure option, and alternative therapies become preferred. Although complete closure is usually accomplished with a single coil in children, multiple coils are frequently needed for complete closure in the adult. Although coil embolization may occur, the snare-assisted technique is almost always successful at percutaneous removal of the coil.
2. The **ADO**, a cone-shaped plug occluder made of thrombogenic wire mesh delivered with a 5F to 7F venous system, is the **preferred device for percutaneous closure of moderate to large PDAs**. The ADO stents the PDA, and blood is forced to flow through the center of the device, which is lined with thrombogenic wire mesh. The PDA then essentially clots off. Advantages include simple implantation, ability to retract the ADO into the sheath and redeploy if needed, and high success rates. There is an 89% occlusion rate on postprocedure day 1 and 97% to 100% complete occlusion after 1 month.
3. **Complications** of transcatheter closure are rare. The most common complication is embolization of the coil or device. Embolized coils can usually be retrieved; but even when this is impossible, adverse consequences are rare. Other

potential complications include flow disturbance in the pulmonary artery or aorta from device protrusion, hemolysis from high-velocity residual shunting, vascular access complications, and infection.

B. Surgical closure. In 1938, the first successful closure of a PDA was performed, which, coincidentally, was the first repair of a congenital heart defect. Surgical closure is the most effective method for complete closure and is usually performed without cardiopulmonary bypass by double ligation and division of the PDA. Ligation may be performed without division, but there is a risk of recanalization of the PDA in up to 20% of cases. In neonates and premature infants, ligation without division is performed because of the small size of the structures. With continued advances in percutaneous closure devices, **surgery has become second-line therapy for most adults with PDAs**. If surgery is necessary, the procedure is > 95% successful and has a low complication rate. The operative mortality rate is < 1%. However, the thoracotomy approach can be painful for adults and necessitates inpatient recovery. Newer surgical techniques such as transaxillary thoracotomy and video-assisted thorascopic ligation have improved surgical morbidity.

C. Medical therapy. In adults, medical therapy is ineffective to close a PDA. Medical therapy is indicated to prevent and treat complications of PDA, including heart failure, atrial arrhythmias, and pulmonary hypertension. **The most recent guidelines from the American Heart Association (AHA)** recommend antibiotic prophylaxis for endarteritis only in the setting of transcutaneous closure of the PDA for 6 months after the procedure; and prophylaxis is not recommended for those with repaired PDA without residual shunt.

D. Follow-up. If immediate duct closure is demonstrated after the procedure, a 6-month follow-up with TTE should suffice to assess for residual flow through the PDA. If residual shunt exists after the procedure, TTE should be performed every 2 to 3 months and early repeat attempt of complete closure considered, depending on the size of the residual shunt or the presence of hemolysis. For long-term follow-up, annual transthoracic echocardiograms are adequate.

VII. COARCTATION OF THE AORTA.

Coarctation of the aorta (CoA) has been found at autopsy in approximately 1 in every 1,550 individuals. It accounts for 5% to 10% of congenital heart disease and occurs more frequently in whites (7:1) and males (2:1). The disorder is typically diagnosed in childhood but may go undetected well into adulthood. Most patients develop persistent systemic hypertension, often as children, and are at risk for premature coronary artery disease. Cases usually occur sporadically, but an autosomal-dominant inheritance pattern has been observed. It is frequently associated with bicuspid aortic valve, and coarctation should be excluded in patients with bicuspid aortic valve and hypertension. Coarctation also occurs in 15% to 35% of patients with Turner's syndrome. Potential catastrophic complications include aortic rupture or dissection and cerebral berry aneurysm rupture. The mean survival for unrepaired patients is 35 years, with a 25% survival rate beyond 50 years.

VIII. ANATOMY.

CoA usually consists of a **narrowing in the region of the ligamentum arteriosum**, the remnant of the ductus arteriosus, just distal to the origin of the left subclavian artery. Most coarctations, therefore, are juxtaductal. The exact anatomy, however, varies, and the coarctation may include a long segment, the transverse arch, or the abdominal aorta. Rarely, tortuosity of the arch is identified. The main anatomic substrate is a prominent posterior shelf of the aorta, composed predominantly of thickened media.

A. Embryology. The exact embryonic origin remains uncertain, but two main theories exist. The first suggests that the narrowing is caused by aberrant ductal tissue

that constricts the aorta at time of ductal closure. The second proposes that aortic hypoplasia develops as a consequence of reduced blood flow in utero.

B. Associated cardiac defects include **bicuspid aortic valve** in 50% to 85% of cases, valvular and subvalvular aortic stenoses, ventricular septal defects, PDA, and congenital malformations of the mitral valve (i.e., smaller orifice, supravalvular ring, and parachute mitral valve resulting from a single papillary muscle). Multiple left-sided heart lesions may be associated with CoA and are often referred to as the Shone complex.

C. Associated extracardiac defects include intracranial aneurysms, especially within the circle of Willis (3% to 5% of cases), hemangiomas, hypospadias, and ocular defects.

IX. CLINICAL PRESENTATION

A. Symptoms. For patients with CoA who survive to adulthood, symptoms are usually negligible and nonspecific. Patients may complain of headaches, nosebleeds, cool extremities, leg weakness, or claudication with exertion. More serious manifestations include angina and heart failure.

B. Physical examination

1. A thorough cardiovascular examination may identify a systolic ejection murmur at the left upper sternal border that radiates to the intrascapular area located immediately anterior or posterior to the CoA. The murmur may be longer in systole and even continue into diastole, depending on the degree of obstruction. Increased flow through the collateral intercostal arteries can produce a continuous murmur appreciated diffusely over the precordium.
2. Upper extremity hypertension is often present, usually in conjunction with **diminished and delayed femoral pulsations**. CoA should always be considered in the differential diagnosis of refractory hypertension, especially in younger patients.
3. Funduscopic examination may demonstrate a "corkscrew" tortuosity of the retinal arterioles.

X. DIAGNOSTIC TESTING

A. The **ECG** is frequently normal but may demonstrate manifestations of long-standing hypertension, such as left ventricular hypertrophy and left atrial enlargement.

B. Chest radiography. Cardiomegaly, dilated ascending aorta, and prominent pulmonary vasculature are common. **Rib notching** usually develops by 4 to 12 years of age and is caused by enlarged intercostal collaterals. The **classic "3" or inverted-E sign is pathognomonic** for CoA and is created by a dilated left subclavian artery above the CoA and poststenotic dilation of the aorta below the CoA.

C. Echocardiography is most useful in infants and children. In adults, the suprasternal notch view is most helpful; color Doppler can be used to localize the site of turbulence. Continuous wave Doppler can assess the pressure gradient. If severe narrowing is present, persistence of flow in diastole (widening of the flow profile from systole into diastole) is seen by continuous wave Doppler in the aorta below the coarctation, such as in the abdominal aorta. This is a useful method to ascertain the presence of significant coarctation, even if imaging the direct site of the obstruction is impossible. A complete study should measure left ventricular size and ascending aortic size, determine aortic valve anatomy and function, and identify any potential associated congenital anomalies. TEE can also better define the anatomy if TTE proves inadequate.

D. MRI provides excellent anatomic and hemodynamic information. MRI is increasingly utilized as a first-line investigation before catheterization, particularly in adults. This enables the precise anatomy to be delineated and helps in the decision making regarding surgery or catheterization as treatment options. Serial MRI scans may be

used to follow results of therapeutic procedures. It is also useful in evaluating the intracranial vessels for associated berry aneurysms.

E. Cardiac catheterization provides excellent image data and pressure information and is often more reliable than echocardiography in adults. An **aortic angiogram** in left anterior–oblique or caudal and direct lateral projections usually best defines the lesion. Pressures should be obtained in the left ventricle and the ascending aorta, and the gradient across the lesion should be measured. A **pullback pressure of > 20 mm Hg** signifies hemodynamic significance and usually warrants intervention if concomitant clinical factors allow. A **gradient of > 50 mm Hg** generally mandates intervention. The presence of collateral vessels may falsely diminish the gradient.

XI. THERAPY. Several factors need to be taken into account when deciding on optimal therapy for CoA, including the age of the patient, the anatomy of the coarctation, any prior CoA operations, and the local surgical expertise. Whatever mode of treatment is chosen, the presence of postprocedural upper extremity hypertension influences survival.

A. In general, **medical therapy** for CoA has very limited utility, but it may be useful in a supportive role along with mechanical treatment. Hypertension should be medically treated, with the goal of controlling blood pressure and preventing end-organ damage.

B. Percutaneous management

1. **Percutaneous balloon angioplasty** is generally less effective than surgery for treatment of primary coarctation. Neonates and infants treated with angioplasty experience high rates of recurrent CoA (about 50% to 60%) and aneurysm formations (5% to 20%); therefore, surgical repair is preferred in this patient population. Likewise, balloon angioplasty of the unoperated coarctation in adults is controversial, with data suggesting higher rates of restenosis and aneurysm formation compared with surgical repair. Procedural complications can include acute aortic rupture (rare), aortic dissection, femoral artery trauma, recurrent coarctation (8%), and aneurysm formation (8% to 35%). The suspected mechanism for late aneurysm formation is intimal tear at the site of cystic medial necrosis within the coarctation site. It should be noted that the clinical impact of aneurysm formation is unclear, as most defects are small and have a low risk of rupture. Percutaneous angioplasty, however, is the preferred therapy for recurrent postsurgical coarctation. The procedure is successful in reducing the gradient to < 20 mm Hg in approximately 80% of interventions, with only a 1.5% incidence of late aneurysm formation.
2. **Stent implantation.** Theoretically, stent implantation may mitigate the development of aneurysm or dissection for a few reasons. By apposing the torn intima to the media and through dispersion of force, stenting may limit vascular trauma. It can also oppose the vascular recoil of the coarcted segment and avoid overdilation. By allowing the use of smaller balloons and graded inflations in staged procedures, stents may also reduce rates of aneurysm formation. Early and intermediate outcomes are promising, with a good safety and efficacy profile as well as lower rates of restenosis and aneurysm formation compared with balloon angioplasty. Despite the lack of long-term outcome data, stenting has become the preferred treatment modality in adults and adult-sized adolescents with native CoA. For recoarctation, balloon angioplasty with or without stenting is preferred in adults as well, as long as the anatomy is suitable.

C. Surgery remains the therapy of choice in neonates and infants. Three types of surgical repair have been used for correction of CoA: resection of the stenosed segment with end-to-end anastomosis, use of a subclavian flap, and patch aortoplasty. The approach with the best long-term outcome and sustained resolution of obstruction has been resection of the stenosed segment with end-to-end anastomosis. This approach carries with it the lowest risk of recurrent CoA (3%) and late aneurysm

formation (rare). Paradoxical hypertension and bowel ischemia may occur in the postoperative period. Major surgical complications include paraplegia caused by perioperative spinal cord ischemia (0.4% to 1%), residual coarctation, aneurysm formation at the site of repair, and, rarely, death. Survival rates of > 90% at 10 years and 84% at 20 years have been reported. Late deaths after surgical repair are related primarily to coronary artery disease, CHF, and aneurysm rupture. Young age favorably influences outcomes after surgery.

XII. FOLLOW-UP. Lifelong follow-up is indicated after the diagnosis of CoA is established, especially after any type of mechanical repair. Key issues to be cognizant of include the progression of hypertension either at rest or with exercise, development of CoA recurrence, aneurysm formation, left ventricular dysfunction, and associated aortic valve dysfunction when bicuspid valve is present. In patients repaired at older ages, hypertension commonly persists despite treatment by percutaneous intervention or surgery. Serial echocardiography is an important component of follow-up. Advanced imaging modalities such as computed tomography or MRI are used increasingly post repair to screen for aortic wall complications, with a preference for MRI given the radiation and contrast issues. Therefore, these patients should be considered "treated" and not "cured" despite repair.

CHAPTER 32

Matthew A. Cavender
Richard A. Krasuski

Complex Congenital Heart Disease

I. TETRALOGY OF FALLOT (TOF). TOF is the most common form of cyanotic heart disease. It occurs in approximately 1 in 3,000 live births and accounts for 10% of congenital heart disease in infants. It is also the most common congenital heart disease requiring surgical correction in the first year of life. The earliest description of TOF dates back to the 17th century; however, Fallot is credited with describing the classic features of the disease in 1888. Surgical treatment for TOF did not become available until well into the 20th century, and it dramatically improved life expectancy. The **current reparative approach has shifted from palliative shunt procedures to primary surgical repair**, most recently with valve-sparing techniques and usually performed in infancy. Without surgical intervention, only about 10% of patients survive beyond the age of 20 years. Adults with TOF usually have undergone surgical repair or palliation. A wide and complex spectrum of TOF exists including association with pulmonary atresia, absent pulmonary valve, and atrioventricular (AV) canal defects. Classic "simple" TOF is discussed here.

A. Anatomy

1. **Anterocephalad deviation of the outlet septum** results in four defining features:
   - **(a)** Right ventricular (RV) outflow tract obstruction
   - **(b)** Nonrestrictive ventricular septal defect (VSD)
   - **(c)** Aortic override of the ventricular septum (> 50% over the right ventricle)
   - **(d)** Right ventricular hypertrophy (RVH)
2. **Associated defects.** Anomalous origin of the left anterior descending coronary artery from the right coronary artery (5%) or a prominent conal branch from the right coronary artery can occur. These vessels cross the RV outflow tract. This anatomic feature is important to surgeons because infundibular resection or future conduit placement may be needed in this location and can lead to inadvertent arterial damage. Right aortic arch occurs in 25% of cases. A secundum atrial septal defect (ASD) occurs in 15% of cases, completing the pentalogy of Fallot. Persistent left superior vena cava is found in 5% of patients. Among adult patients, aortic insufficiency can occur naturally from long-term dilation of the aortic root, after endocarditis or as a postoperative sequela. Rare complications include pulmonary hypertension, supravalvular mitral stenosis, and subaortic stenosis. There is an association with deletion in the chromosome 22q11 region, which is also present in DiGeorge syndrome and/or velocardiofacial syndrome.

B. Clinical presentation

1. **Patients who have not undergone surgical repair** have variable clinical features depending on the amount of RV outflow tract obstruction, degree of aortic override, and, to a lesser extent, systemic vascular resistance, all of which dictate the amount and direction of shunting across the VSD.
   - **a.** With severe RV outflow tract obstruction, patients have central cyanosis and clubbing by 6 months of age. Hypoxic "spells" may be seen and are characterized by tachypnea, dyspnea, cyanosis, or even loss of consciousness or

death. If the obstruction is mild, however, the shunt through the VSD may be left-to-right, resulting in "pink tet" with minimal symptoms.

b. On physical examination, the patient is usually cyanotic and clubbed. A prominent RV impulse may be appreciated because of equalization of right and left ventricular pressures. A lift may be palpated under the right sternoclavicular junction in patients with a right-sided arch. The first heart sound (S_1) is usually normal, but the second heart sound (S_2) is often single because of an inaudible P_2. Auscultation is notable for a prominent systolic ejection murmur at the left upper sternal border, possibly with an associated thrill. The shorter the murmur, the more severe the infundibular pulmonary stenosis. The murmur of aortic insufficiency may be audible along with an aortic click resulting from a dilated overriding aorta. Continuous murmurs may be heard due to aortopulmonary collateral vessels. The presence of these vessels is more likely in the setting of pulmonary atresia, but they can also be acquired if RV outflow tract stenosis develops gradually.

2. Most adult congenital patients will have undergone surgical repair with or without a prior palliative procedure. The term "**palliation**" (as opposed to "repair") in these patients refers to a surgical procedure that consists of a **systemic-to-pulmonary artery shunt** (modified Blalock-Taussig shunt, classic Blalock-Taussig shunt, Potts shunt, or Waterston shunt; Table 32.1). These procedures are initially performed to supplement the deficiency of antegrade pulmonary

TABLE 32.1 Index of Postoperative Anatomy among Adult Patients with Congenital Heart Disease

Underlying pathology	Procedure	Notes
Single ventricle Hypoplastic left heart Tricuspid atresia	**1. Norwood**	Incorporation of native aorta and pulmonary artery (one of which may be hypoplastic or atretic) to produce a "**neo-aorta**" for the single ventricle
Pulmonary atresia with intact ventricular septum Unbalanced complete AV canal defect		Main pulmonary artery is transected from the heart Pulmonary flow is maintained with placement of a **Blalock-Taussig shunt** **Atrial septectomy** is often performed to allow complete mixing at the atrial level
	2. Bidirectional Glenn	Usually performed at 4–6 mo if pulmonary arterial anatomy, pressures, and resistances are adequate Anastomosis of the **superior vena cava to the pulmonary artery**, usually with takedown of a previously placed systemic-to-pulmonary artery shunt and repair of pulmonary arterial branch stenosis if necessary Term *bidirectional* is used in descriptions of this procedure because both right and left pulmonary arteries usually remain in continuity

TABLE 32.1 Index of Postoperative Anatomy among Adult Patients with Congenital Heart Disease (*Continued*)

Underlying pathology	Procedure	Notes
	3. Fontan	Usually performed at 1–5 y depending on growth of vasculature and cyanosis Anastomosis of **inferior vena cava to the pulmonary artery** by intra-atrial lateral tunnel or extracardiac conduit Pulmonary blood flow is achieved passively, without the assistance of a ventricular pumping chamber
dTGA (ventriculoarterial discordance)	**Rashkind**	**Atrial balloon septostomy** to create mixing of systemic and pulmonary circulation
	Blalock-Hanlon	Surgical atrial septectomy
	Mustard or Senning (atrial switch)	Baffle material (Mustard) or native atrial tissue (Senning) used to direct pulmonary venous blood → right ventricle → aorta; systemic venous blood → left ventricle → pulmonary artery
	Jatene (arterial switch)	Great arteries are transected and reanastomosed to the appropriate ventricle
		Coronary arteries are removed with a button of surrounding tissue and reimplanted to the appropriate sinuses
	Rastelli	For dTGA with VSD and pulmonary outflow tract obstruction
		VSD patch closure that directs left ventricular blood across the VSD to the aorta
		Pulmonary valve is oversewn
		Valved conduit from the right ventricle to the pulmonary artery to create RV outflow
Deficient pulmonary artery or RV outflow tract Pulmonary atresia Tetralogy of Fallot with hypoplastic pulmonary arteries	**Classic Blalock-Taussig** **Modified Blalock-Taussig** **Waterston shunt** **Potts shunt**	Native subclavian artery anastomosed to the right or left pulmonary artery Expanded polytetrafluoroethylene (Gore-Tex) material connecting the subclavian or innominate artery to the pulmonary artery Anastomosis between the ascending aorta and right pulmonary artery Anastomosis between the descending aorta and left pulmonary artery

AV, atrioventricular; RV, right ventricular; TGA, transposition of the great arteries; VSD, ventricular septal defect.

blood flow and are taken down at the time of complete repair. The latter two procedures have been abandoned owing to associated uncontrolled pulmonary blood flow and the subsequent development of pulmonary hypertension.

a. Patients who have undergone palliative repair alone have variable clinical findings depending on the type of palliation performed. In those who have undergone a classic Blalock-Taussig shunt, the brachial pulse on that side may be diminished or absent. If patent, shunts can produce a continuous murmur. Continuous murmurs can also result from aortopulmonary collaterals. Branch pulmonary artery stenosis at prior shunt insertion sites can produce unilateral systolic or continuous murmurs. Systolic ejection murmurs may be audible depending on the degree of antegrade flow across the outflow tract.

3. Complete (or total) repair consists of patch closure of the VSD and variable degrees of RV outflow tract resection and reconstruction. It may involve pulmonary valvotomy, RV outflow tract patch augmentation, transannular patch enlargement, or placement of a right ventricle–to–pulmonary artery conduit (i.e., bioprosthetic or homograft). Distal branch pulmonary artery stenosis may have been repaired, or residual lesions may be present. These patients typically have first undergone a palliative shunt procedure, but the current surgical approach has shifted to primary complete repair in infancy.

a. Patients are often asymptomatic. They may present with late symptoms such as dyspnea, exercise intolerance, palpitations, signs of right heart failure, or syncope.

b. The jugular venous pressure is usually normal unless there is RV dysfunction, in which case elevated jugular venous pressure with a prominent *a* wave is seen. The brisk pulse of aortic insufficiency may also be appreciated. On palpation, there may be an RV lift or a lift under the right sternoclavicular junction when the arch is right-sided. Some degree of turbulence almost always remains across the RV outflow tract and produces a variable systolic ejection murmur at the left upper sternal border, with radiation to the back and peripheral lung fields. Of importance is the presence of associated pulmonary insufficiency. This, even if severe, may occasionally be inaudible due to low-pressure hemodynamics. It is generally appreciated at the left upper sternal border, sometimes producing a to-and-fro murmur together with the outflow tract murmur. A high-frequency systolic murmur at the left lower sternal border suggests the presence of a residual VSD (often due to a small leak in the VSD patch). Continuous murmurs from collateral formation or prior shunts may be appreciated. The diastolic murmur of aortic insufficiency may also be heard.

C. Laboratory examination

1. Chest radiographic findings depend on the surgical history. The presence of a right aortic arch may be confirmed. A concave deficiency of the left heart border reflects various degrees of pulmonary arterial hypoplasia. Upturning of the apex from RVH causes the classic finding of a "boot-shaped" heart. Pulmonary vascular markings may vary throughout the lung fields, depending on associated branch pulmonary artery stenosis and relative blood flow. Calcification or aneurysmal dilation of surgical conduits or RV outflow tract repair may be visible on plain radiographs.

2. An **electrocardiogram** usually demonstrates sinus rhythm with RVH. Both atrial and ventricular rhythm disturbances can be present. The QRS axis is usually normal or rightward. If left axis deviation is present, an associated AV canal defect should be suspected. A patient who has undergone surgical repair typically has right bundle branch block. **A QRS duration of > 180 milliseconds is a predictor of sustained ventricular tachycardia and sudden cardiac death**.

D. Diagnostic testing

1. Echocardiography

a. For a child or young adult, transthoracic echocardiography may be the only modality necessary for diagnosis. For adults or patients who have undergone surgical intervention, catheterization or magnetic resonance imaging (MRI) may be necessary in order to identify the presence and location of residual lesions.

(1) Adequate views are obtained of the right heart, RV outflow tract, and proximal pulmonary arteries. Helpful views to identify a residual VSD or the presence of aortic insufficiency include the parasternal long-axis, parasternal short-axis, and apical four-chamber views. Further definition of residual lesions in the branch pulmonary arteries may be possible with a high parasternal short-axis view.

(2) Palliative shunts are often best visualized in the suprasternal notch view where the subclavian arteries course distally.

(3) Continuous flow is typically demonstrated with color Doppler techniques. Less common shunts may be difficult to image in adult patients. Aortopulmonary collateral vessels are extremely difficult to visualize, but may be seen in suprasternal notch views of the descending aorta.

b. Transesophageal echocardiography may allow improved imaging of the intracardiac anatomic structures in adults, but limitations often remain with regard to the distal pulmonary arteries, and additional testing is frequently necessary.

2. Cardiac magnetic resonance (CMR) imaging is considered the gold standard for evaluating the right ventricle and quantitating pulmonary insufficiency in these patients. It can demonstrate the presence of scar, distal pulmonary arterial anatomy, and RV aneurysms, as well as other associated defects. It can also provide hemodynamic information about residual lesions. Previously placed shunts and possibly aortopulmonary collateral vessels can be identified as well. The anatomic information may be sufficient to proceed with surgical treatment or to guide the interventional cardiologist in planning a transcatheter procedure.

3. Cardiopulmonary testing should be performed as a baseline study and with progression of symptoms. It is useful in determining the timing for reintervention in the setting of RV volume overload secondary to free pulmonary insufficiency.

4. Quantitative pulmonary flow scans are useful to determine discrepancies in pulmonary flow that may be caused by branch pulmonary artery stenosis. These scans also provide objective baseline clinical information when obtained after surgical or transcatheter intervention.

5. The role of **cardiac catheterization** is decreasing with the advent of other imaging modalities, but can be helpful in assessing residual shunts and pulmonary hypertension.

a. Right heart catheterization. Residual shunts are actively sought at the atrial and ventricular levels. The pulmonary arteries and branches are evaluated extensively in search of peripheral pulmonary stenosis. Findings at right heart catheterization and their clinical significance are as follows:

(1) RV pressure is generally systemic in a patient who has not undergone surgical repair.

(2) After surgical repair, elevated RV pressure suggests the presence of residual obstructive lesions, the levels of which are to be documented.

(3) Careful pullback recordings are performed from the branch pulmonary arteries to the right ventricle because stenosis at each level is possible.

(4) The presence of stenosis at a prior shunt site is expected.

(5) RV end-diastolic pressures may be elevated in the setting of pulmonary insufficiency.

b. Left heart catheterization is performed if noninvasive studies suggest residual VSD.

(1) Angiography includes a cranialized right ventriculography and possibly selective pulmonary arterial injections if hemodynamic findings suggest stenosis.

(2) Left ventriculography better demonstrates residual VSD in the presence of subsystemic RV pressures.

(3) Aortic root injection demonstrates the presence of aortic insufficiency, confirms the presence of grossly abnormal coronary artery origins or branching patterns, and reveals prior surgical shunts or aortopulmonary collateral vessels. If present, shunts and collateral vessels are best visualized in the posteroanterior and lateral projections after selective injection by hand.

(4) Selective coronary angiography is recommended in the care of adult patients to exclude acquired coronary artery disease and to identify the path of any anomalous coronaries before surgical intervention. **The anomaly that is not to be missed is the left anterior descending artery originating from the right coronary artery**—it crosses the RV outflow tract anteriorly and can be damaged during surgery.

E. Therapy and follow-up care

1. Medical treatment

a. If an adult has **not been surgically treated or has undergone palliative treatment**, a relatively well-balanced situation must exist. However, the following problems are to be expected.

(1) Long-term effects of RV outflow obstruction
(2) Progressive infundibular pulmonary stenosis
(3) Exposure of the pulmonary circulation to systemic shunt flow
(4) Development of distal pulmonary arterial stenosis, typically at shunt sites
(5) Erythrocytosis
(6) Chronic hypoxemia
(7) Pulmonary hypertension
(8) Paradoxical emboli
(9) Atrial and ventricular arrhythmias
(10) Increased risk of aortic insufficiency over time
(11) Endocarditis

b. Follow-up care increasingly involves **patients who have undergone surgical repair** and management of residual postoperative lesions.

(1) These patients are at increased risk for **sudden cardiac death**. Atrial and ventricular rhythm disturbances are common in the postoperative patient. Frequent Holter monitoring is warranted for this reason. Atrial tachyarrhythmias are found in up to one-third of patients and are predictive of morbidity and mortality. If patients are found to have nonsustained ventricular tachycardia, an electrophysiologic study and possibly an implantable cardioverter–defibrillator implantation can be considered. Atrial and ventricular arrhythmias may be the presenting problem for post-repair patients when a component of the repair is failing. There are no data to support prophylactic antiarrhythmic therapy to lower risk of sudden death in this patient population. An increased incidence of ventricular rhythm abnormalities has been associated with RV volume overload from pulmonary insufficiency and with QRS prolongation > 180 milliseconds (QRS duration correlates with degree of RV dilation).

(2) Pulmonary insufficiency can be tolerated for years, even decades, but chronic volume loading of the right ventricle can lead to diminished exercise tolerance, dysrhythmias, and **right heart failure**. Pulmonary

insufficiency is the most common indication for redo surgery after an initial repair.
(3) Residual VSD
(4) Progressive dilation of the ascending aorta
(5) Residual RV outflow tract gradient
(6) RV outflow tract aneurysm at previous patch site

c. Recent **infective endocarditis guidelines** have departed considerably from prior iterations such that antibiotic prophylaxis is recommended only for those who are at highest risk for adverse outcomes from endocarditis. Specifically, prophylaxis is still appropriate for patients with TOF who are unrepaired, including those who have undergone a palliative procedure. For patients with TOF who have undergone total repair, antibiotic prophylaxis is now recommended only for 6 months following the placement of prosthetic material or device or if there is a residual defect at, or adjacent to, the site of prosthetic material (VSD patch leak, for example). If the pulmonary valve has been replaced or repaired with prosthetic material, antibiotic prophylaxis is appropriate as well.

2. The primary therapeutic consideration for patients with TOF is **surgical intervention**—either repair or reintervention.
   a. The goal of **total repair** is to relieve the outflow tract obstruction while maintaining competency of a preferably native pulmonary valve with closure of the VSD. Some younger patients need extensive reconstruction of the RV outflow tract with early placement of a bioprosthetic valved conduit or homograft. In time, these usually become restrictive to flow and/or are insufficient. The result is progressive right heart hypertrophy, fibrosis, and failure if revision is not performed.
   b. A common indication for **reintervention** is pulmonary valve replacement (PVR) for severe pulmonary valve insufficiency. The ideal timing for PVR, however, remains controversial. Cardiac MRI may be helpful in determining optimal timing, and there is evidence to support pursuing pulmonic valve replacement before the RV end-diastolic volume index reaches 160 mL/m^2.
   c. Other indications for **reintervention** include the replacement or revision of conduits/homografts in the presence of symptoms, residual VSD with reasonable shunt (approximately 1.5:1), RV pressures greater than two-thirds of systemic pressures because of residual obstructive lesions, progressive aneurysmal dilation of RV outflow tract patch, residual systemic–pulmonary shunts with left ventricular volume overload, clinically significant arrhythmias, symptomatic or progressive aortic insufficiency, and dilated aortic root > 5.0 cm.
3. Although the mainstay of therapy has been surgical, **transcatheter techniques** are increasingly used to treat patients in certain situations. For the most part, transcatheter therapies for adults with TOF are limited to patients who have undergone prior surgical treatment, with attention to residual obstructive lesions in the main pulmonary artery, right ventricle–to–pulmonary artery conduit, or distal pulmonary arteries. Prior shunt sites may become stenotic with time and necessitate balloon angioplasty and possibly stent placement. Residual VSD and ASD may be closed percutaneously in select situations. Percutaneous pulmonic valve replacement has been approved for use both in Europe and the United States. The Melody valve (Medtronic; Minneapolis, MN) is a therapeutic option available for selected patients with stenotic or regurgitant conduits 23 mm or less in size.

II. COMPLETE TRANSPOSITION OF THE GREAT ARTERIES (D-TGA).

This is a relatively common congenital anomaly that occurs with a prevalence of 20 to 30 in 100,000 live births and is found more often in males (2:1). It is not associated with other syndromes and does not tend to cluster in families. Although it represents **5% to 8% of**

all congenital heart disease, it accounts for **25% of deaths in the first year of life**. Adult patients almost invariably have undergone prior surgery and carry with them important morbidities that require ongoing surveillance and care.

A. Anatomy

1. The defining feature of this anomaly is **ventriculoarterial discordance**, in which there is an abnormal alignment between the ventricles and great arteries. Hence the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle, creating two parallel circuits instead of one in series. Deoxygenated blood flows from the right atrium across a tricuspid valve → right ventricle → aorta, whereas oxygenated blood flows from the left atrium across the mitral valve → left ventricle → pulmonary artery. Unless there is bidirectional shunting at the atrial (ASD), ventricular (VSD), or great artery level (patent ductus arteriosus) to allow mixing of blood, this anatomy is incompatible with life (Fig. 32.1).
2. There is an abnormal spatial relationship between the great arteries such that instead of the normal spiral configuration, they run parallel to one another. The **aorta is rightward and anteriorly displaced**, whereas **the pulmonary artery occupies a position more leftward and posterior**. This is the most common pattern, but other configurations can also be seen such as side-by-side great arteries with the aorta to the right or an aorta directly anterior to the pulmonary artery.
3. Associated cardiac anomalies include **VSD in 40%** to 45% of cases (usually perimembranous but can involve any portion of the interventricular septum), **left ventricular (or subpulmonary) outflow tract obstruction in 25%**, aortic coarctation in 5%, patent foramen ovale (PFO), and patent ductus arteriosus. Patients with these associated cardiac anomalies are considered to have **complex** transposition, whereas patients without these associated anomalies are considered to have simple transposition.
4. This lesion is also referred to as "dTGA," in which the "d" refers to the dextroposition of the bulboventricular loop, which is characterized by a right-sided right ventricle.
5. The coronary anatomy in dTGA is variable. The aortic sinuses are described according to their relationship to the pulmonary artery, such that the "facing

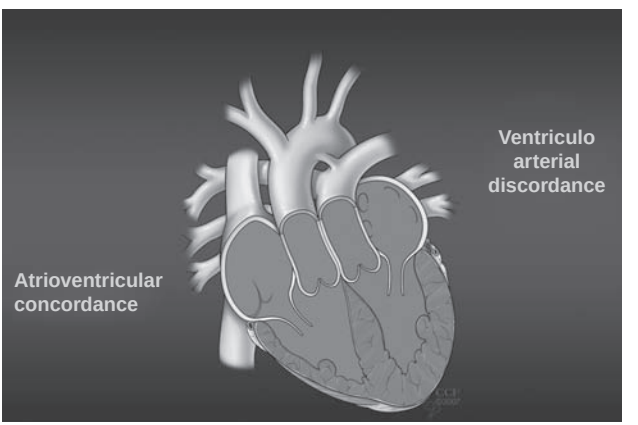

FIGURE 32.1 Complete (d) transposition of the great arteries.

sinuses" are closest to the pulmonary artery. The most frequent coronary arrangement is when the "left-facing" sinus gives rise to the left main coronary artery, whereas the "right-facing" sinus gives rise to the right coronary artery.

B. Natural history and surgical repair

1. Without surgical intervention, survival beyond infancy is dismal, with 89% mortality by the first year of life and worse outcomes for those without an associated lesion to allow for adequate mixing of blood. At birth, infants are treated with intravenous prostaglandin E to keep the ductus arteriosus open and some may undergo a **Rashkind procedure** (refer Table 32.1) to improve oxygenation until definitive surgery can be performed.
2. Adults invariably have undergone some type of cardiac surgery, although in rare cases they may present with Eisenmenger physiology (see subsequent text) if a "balanced" situation exists with a concomitant large VSD and pulmonary vascular disease. Surgical repairs include the atrial switch procedure **(Senning or Mustard operation)**, the **arterial switch** procedure (Fig. 32.2), or the **Rastelli operation** (Table 32.1).

C. Clinical presentation

1. The clinical presentation of the surgically repaired patient with dTGA depends on the type of previous surgery. Although no longer cyanotic, these patients have a host of mid- to late-term morbidities that require lifelong surveillance. Patients who have undergone an arterial switch procedure are approaching adulthood only now and presenting in adult congenital cardiology clinics.
2. **Atrial switch**
   a. Patients who have undergone an atrial switch operation often report New York Heart Association (NYHA) functional class I–II symptoms, but on exercise testing may have significant exercise intolerance. They have a systemic right ventricle, which, over time, can develop systolic dysfunction and progressive tricuspid regurgitation. These patients may present with signs and symptoms of congestive heart failure—the most common cause of death. Arrhythmias are common and patients may present with palpitations,

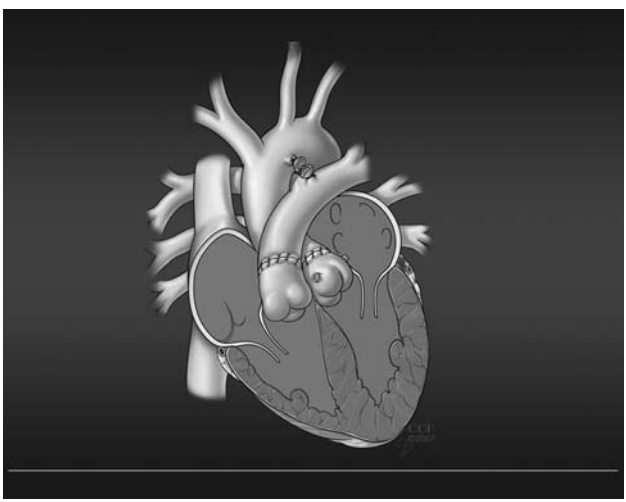

FIGURE 32.2 Arterial switch operation.

presyncope, or syncope. Venous baffle obstruction can lead to peripheral edema, hepatomegaly, ascites, and fatigue due to low cardiac output. The obstruction of the superior limb can produce a superior vena cava syndrome. Pulmonary venous baffle obstruction can lead to fatigue, exertional dyspnea, and chronic cough. Baffle leaks are often asymptomatic, but large leaks can lead to intracardiac shunting and cyanosis.

b. On physical examination, focus should be on signs of AV regurgitation and heart failure. There may be an RV heave at the left sternal border on palpation. S_2 is loud at the second left intercostal space from an anterior aorta. Audible splitting of the S_2 may indicate the development of pulmonary hypertension.

3. Arterial switch

a. The majority of these patients are asymptomatic with NYHA functional class I symptoms. Arrhythmias are not a significant problem with this subset. Few will present with chest pain, and in these patients ischemia must be ruled out.

b. The physical examination is sometimes notable for turbulence across the RV outflow tract, which may be palpated as a thrill. The diastolic murmur of aortic insufficiency should also be sought.

4. Rastelli operation

a. Both atrial and ventricular arrhythmias are mid- to late-term complications, and these patients may present with palpitations or syncope. Conduit obstruction may manifest as insidious exercise intolerance, dyspnea, or new-onset arrhythmias. On physical examination, the character of the pulmonic ejection murmur should be carefully noted to evaluate for conduit obstruction.

D. Laboratory examination

1. The **chest radiograph** of patients with dTGA displays a narrow mediastinum due to the parallel orientation of the great arteries. The cardiothoracic silhouette is normal. The pulmonary vasculature is normal in patients without pulmonary hypertension. The right ventricle–to–pulmonary artery conduit in patients who have undergone a Rastelli procedure may be visualized on plain radiograph due to calcification.

2. In patients who have undergone an atrial switch operation, the **electrocardiogram** may display an ectopic atrial or junctional rhythm due to loss of sinus node function. There is usually right-axis deviation and RVH as a result of the systemic position of the right ventricle. In patients who have undergone arterial switch, RVH is distinctly abnormal and suggests pulmonary outflow tract obstruction. After a Rastelli operation, the electrocardiogram is notable for a right bundle branch block and patients may develop complete heart block.

E. Diagnostic testing

1. Transthoracic echocardiography in atrial switch patients can assess the degree of tricuspid regurgitation and estimate RV function. Color Doppler is helpful in detecting baffle leaks or obstruction, although more detailed analysis may require transesophageal echocardiography. For those who have undergone arterial switch, transthoracic echocardiography can assess left ventricular function and help exclude supravalvular and pulmonary artery stenosis. Two-dimensional Doppler can be used to look for conduit stenosis after the Rastelli operation and estimate RV systolic pressures. It can also exclude any residual VSDs in these patients.

2. As in the TOF population, **CMR** imaging has emerged as an invaluable imaging modality for patients with repaired dTGA. For postatrial switch patients, CMR imaging is used to quantify the size and function of the right ventricle, assess tricuspid regurgitation, and evaluate the systemic and pulmonary venous limbs of the atrial baffle for potential obstruction or leaks. In patients who have undergone

arterial repair, right and left ventricular function can be quantitated and both the right and left outflow tracts examined. Focus is placed on the great arteries to look for the presence of supravalvular and branch pulmonary artery stenosis as well as dilation of the neo-aorta. Conduit stenosis and gradients as well as RV size and function can be determined in those who have had a Rastelli operation.

3. **Cardiopulmonary testing** is very useful in detecting subtle clinical changes and decrease in functional capacity. As mentioned previously, there is often a discrepancy between self-reported symptoms and performance on metabolic exercise testing. Patients who have undergone atrial switch often have chronotropic incompetence and may benefit from pacemaker implantation. Stress testing may be useful in patients after arterial switch to detect coronary artery stenosis and resultant ischemia.
4. **Quantitative pulmonary flow scans** are an important part of the diagnostic work-up for suspected pulmonary artery or branch pulmonary artery stenosis in those who have undergone arterial switch repair. It is useful to obtain these scans before and after potential intervention to assess for functional improvement.
5. **Cardiac catheterization** does not have a role in the routine management of these adult patients. It does have a role, however, in the diagnosis and treatment of baffle obstruction and leaks, pulmonary hypertension, pulmonary artery stenosis, coronary artery stenosis, conduit obstruction, and residual VSD.

F. Therapy and follow-up

1. Follow-up should focus on potential late complications after repair and depends on the type of surgery the patient has undergone.
   - **a.** Atrial switch
     - **(1)** Arrhythmias including sinus node dysfunction and intra-atrial reentry tachycardia (frequent Holter monitoring is recommended)
     - **(2)** RV dysfunction
     - **(3)** Tricuspid regurgitation
     - **(4)** Sudden cardiac death
     - **(5)** Baffle obstruction or leak
     - **(6)** Pulmonary hypertension
     - **(7)** Endocarditis
   - **b.** Arterial switch
     - **(1)** Supravalvular or peripheral pulmonary artery stenosis
     - **(2)** Pulmonary outflow tract obstruction
     - **(3)** Neo-aortic regurgitation and aortic root dilation
     - **(4)** Coronary artery stenosis leading to ischemia and sudden death
     - **(5)** Left ventricular dysfunction
     - **(6)** Endocarditis
   - **c. Rastelli operation**
     - **(1)** Atrial and ventricular arrhythmias
     - **(2)** Complete heart block
     - **(3)** Sudden cardiac death
     - **(4)** Left ventricular dysfunction
     - **(5)** Conduit stenosis
     - **(6)** Endocarditis
2. **Medical management**
   - **a.** In the treatment of systemic RV dysfunction, there are limited data to suggest any long-term benefits from applying the evidence-based drugs utilized for left ventricular dysfunction. Despite this, angiotensin-converting enzyme (ACE) inhibitors are often utilized for afterload reduction. β-Blockers should be used with caution in patients after atrial switch repairs, as this could precipitate heart block (due to sinus node and AV conduction abnormalities).
   - **b.** As mentioned previously, the latest **infective endocarditis** guidelines have changed such that in the absence of valve replacement or prosthetic material

used to repair a valve, implantation of prosthetic material within the last 6 months, or prosthetic material accompanied by residual leaks, it is no longer officially recommended that dTGA patients post-repair receive antibiotic prophylaxis.

3. Late intervention options include both surgical and transcatheter procedures and, again, depend on the type of repair. Systemic ventricular failure may ultimately require work-up for orthotopic heart transplantation.
   a. **Atrial switch**
      (1) The procedure of choice in patients with baffle obstruction is transcatheter stent implantation, with best results in the systemic venous baffle. Although technically more challenging, transcatheter dilation of the pulmonary venous baffle can be performed but may require surgical revision. Clinically significant baffle leaks can be treated with catheter-based techniques as well as with septal occluder devices.
      (2) Due to the high prevalence of atrial arrhythmias and sinus node dysfunction, these patients are referred for radiofrequency ablation procedures and pacemaker implantation.
      (3) Conversion to an arterial switch for systemic RV dysfunction or left ventricular "training" by pulmonary artery banding has not been reliably successful in the adult population and has been largely supplanted by cardiac transplantation in many centers.
   b. **Arterial switch**
      (1) Percutaneous balloon angioplasty with or without stent placement is an excellent option for those with pulmonary artery and supravalvular or branch pulmonary artery stenosis with suitable anatomy. Balloon angioplasty being a safe procedure, there is an approximately 15% restenosis rate, with lower risk after stent implantation. The greatest success lies with branch pulmonary artery stenosis.
      (2) Coronary artery stenosis can be treated with both stenting and coronary bypass surgery.
      (3) Severe neo-aortic regurgitation is treated surgically with either valve repair or replacement.
   c. **Rastelli operation**
      (1) All right ventricle to pulmonary artery conduits inevitably fail and require replacement. There is a role for percutaneous stenting of conduit obstruction in some patients, as this can delay the need for surgery. These transcatheter procedures have a risk of stent fracture as well as potential for coronary artery compression, which can lead to catastrophic outcomes in the catheterization laboratory.
      (2) Residual VSD leaks may be amenable to closure by percutaneous means, but often require surgical revision. Clinically significant residual left ventricular outflow tract obstruction is also managed surgically.

III. CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES (ccTGA).

Ventricular inversion or ccTGA is a rare congenital anomaly that occurs in < 1% of children with congenital cardiovascular defects. Among these patients, it is equally rare to have no other associated structural abnormalities. The natural history of ccTGA is gradual congestive failure caused by systemic AV valve insufficiency and systemic ventricular dysfunction, even in the absence of other associated malformations. The presence of associated defects and conduction abnormalities contributes to a further decrease in life expectancy without intervention. Life expectancy is generally good but does not reach normal.

A. Anatomy

1. The defining feature of this congenital abnormality of cardiac looping is **AV and ventriculoarterial discordance**. Blood flows from the right atrium across

a mitral valve → right-sided, morphologic left ventricle → pulmonary artery → lungs → left atrium across a tricuspid valve → left-sided, morphologic right ventricle → aorta (Fig. 32.3).

2. The great arteries are not in their normal configuration and often run parallel to one another instead of crossing. The pulmonary artery is more posterior and rightward than usual and the aorta is more anterior and leftward.
3. The anatomic coronary arteries, like the AV valves, follow their respective ventricles. The left-sided coronary artery resembles the anatomic right coronary artery as it courses in the AV groove and gives rise to infundibular and marginal branches. The right-sided coronary artery resembles the morphologic left coronary artery, which branches into the anterior descending and circumflex arteries (Fig. 32.4).
4. The conduction system likewise follows the respective ventricle, as the right-sided, morphologic left ventricle depolarizes first. Accessory AV nodal tissue is located anteriorly with respect to normal, and the His bundle must traverse

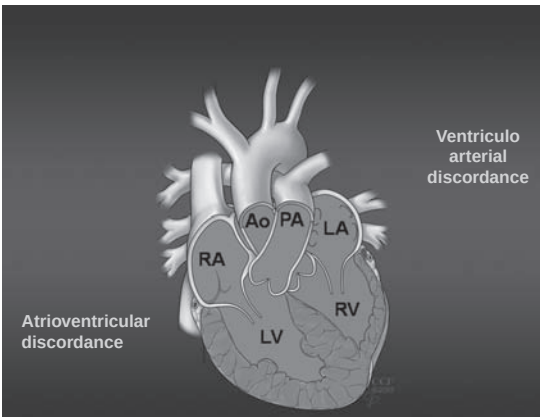

FIGURE 32.3 Congenitally corrected (l) transposition of the great arteries. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

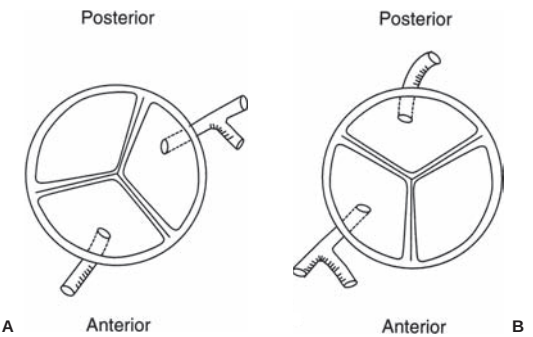

FIGURE 32.4 Schematic representation of coronary artery origins and branching in the normal heart (**A**) and in a congenitally corrected transposition (**B**).

anterior to the pulmonary artery and along the superior margin of a VSD if present. There is increased risk of acquired **complete heart block** in this lesion because of the abnormally placed AV node and its extended course. Approximately 30% of adolescents and adults develop complete heart block, the incidence of which is 2% per year without surgical intervention, with the site of block being within or above the His bundle. Accessory pathways have been described and are typically left-sided in the presence of an Ebstein anomaly–like malformation of the left-sided (tricuspid) AV valve.

5. Isolated ccTGA is the exception. **Associated lesions** are common and are considered in the diagnostic evaluation. They include VSD (70%), pulmonary outflow obstruction (~40% and usually subvalvular), or abnormalities of the left-sided, systemic tricuspid valve. Up to 90% of patients have an abnormality of the tricuspid valve in some form (i.e., dysplastic or Ebstein-like tricuspid valves).

B. Clinical presentation

1. Because physiologic blood flow is preserved, patients may have no symptoms through adulthood in the absence of other structural lesions or associated complications. This scenario is rare, however, because associated lesions commonly dictate the clinical features.
2. Without associated structural abnormalities, **failure of the systemic morphologic right ventricle** with various degrees of systemic AV valve (tricuspid) insufficiency is the norm. In this setting, the patient has nonspecific descriptions of fatigue, shortness of breath, and exercise intolerance or congestive failure. Patients may have **syncope or presyncope** caused by conduction abnormalities or complete heart block.
3. On physical examination, there is a loud A_2 due to an anterior and leftward aorta. The murmurs of a VSD or pulmonary stenosis may also be appreciated. Tricuspid insufficiency can be heard with systemic ventricular failure.

C. Laboratory examination

1. In the usual anatomic configuration of ccTGA, the aorta is anterior and to the left, which produces a **chest radiograph** with a straight left heart border. The left pulmonary artery is not well defined and the ascending aorta is not visible on the right. The chest radiograph may appear normal or reflect the presence of associated lesions, such as increased pulmonary flow from a VSD or decreased pulmonary flow in the setting of pulmonary stenosis. Dextrocardia occurs in approximately 20% of these patients and the diagnosis should be suspected if seen with abdominal situs solitus.
2. The typical **electrocardiogram** shows a left axis deviation. Among pediatric patients, there is loss of the usual Q waves in the precordial leads, with deep Q waves in leads II and aVF reflecting reverse septal activation. A variety of AV node conduction abnormalities may manifest with time and progress to complete heart block.

D. Diagnostic evaluation

1. In most instances, the diagnosis can be made with **echocardiography**. The essential findings of AV and ventriculoarterial discordance must be demonstrated. Imaging may be difficult in the presence of dextrocardia or mesocardia. Close attention must be paid to the morphologic details of each chamber.
   a. The morphologic **right ventricle** is identified on the basis of its **triangular** shape, the presence of **trabeculations and moderator band**, an inferiorly positioned AV valve, and the absence of AV valve attachments to the interventricular septum.
   b. The morphologic **left ventricle** is identified on the basis of its bullet shape, smooth wall, and more superiorly positioned AV valve and presence of AV valve attachments to the interventricular septum. In the case of ccTGA, these relationships are preserved but reversed.

c. There is lack of anatomic continuity between the **left-sided (tricuspid) AV valve and aorta**, but continuity is present between the **right-sided (anatomic mitral) valve and pulmonary artery**. The left-sided AV valve is displaced inferiorly relative to the right-sided (mitral) valve and may appear malformed or have the characteristics of Ebstein anomaly.

d. Apical four-chamber and subcostal images are particularly helpful. The suprasternal notch view is essential in evaluating the great vessels that lie parallel to each other.

e. The **aortic arch** typically lies to the left of midline in the sagittal plane and can often be visualized from the high left parasternal position. Because variations in great vessel position occur, the spatial orientation must be clarified.

f. **Associated defects** (e.g., systemic AV valve insufficiency, VSD, and outflow tract obstruction) with ccTGA must be excluded or defined.

2. **Catheterization is unnecessary** for the diagnosis of ccTGA, but may be helpful in preoperative planning with regard to the hemodynamic significance of associated lesions. In rare instances, ccTGA is diagnosed by catheterization and was not recognized during routine echocardiography. An unusual arterial catheter course is caused by the anterior and leftward position of the aorta in most instances. The left-sided coronary artery typically arises from the posterior sinus and assumes a right coronary branching distribution, whereas the right-sided coronary artery arises from the anterior and rightward sinus and assumes a typical left coronary branching distribution (Fig. 32.4). Because the ventricular septum often lies in the sagittal plane, ventriculography is usually best performed in the straight posteroanterior and lateral projections.

E. Therapy

1. **Medical management** is dictated primarily by the associated malformations.

a. In the rare case of isolated ccTGA, the risk of development of conduction abnormalities is cumulative over time; therefore, periodic Holter monitoring is warranted. Permanent pacemaker placement is often needed.

b. The systemic AV valve and ventricle may show signs of failure that necessitate initiation of heart failure measures in the form of diuretics and afterload reduction, although data are lacking for the use of agents such as ACE inhibitors or β-blockers in systemic right ventricles.

c. Associated lesions such as pulmonary stenosis or atresia, severe systemic AV valve regurgitation, or VSD may likewise contribute to the medical treatment of these patients, but often also necessitate surgical intervention.

d. The recent American Heart Association (AHA) guidelines do not recommend routine antibiotic prophylaxis for these patients unless they have had recent placement of prosthetic material within the preceding 6 months or have a leak at, or adjacent to, the site of a previous prosthesis.

2. **Surgery**

a. Infants and children who are brought to medical attention early often need surgical intervention in the form of relief of pulmonary outflow tract obstruction or placement of palliative shunts, depending on the associated lesions.

b. For selected children, a **double switch** procedure may be performed. An **atrial switch** corrects the AV discordance by baffling atrial blood to the appropriate ventricle (i.e., oxygenated blood diverted from the left atrium rightward to the right-sided left ventricle and vice versa by the Mustard or Senning procedure). **Arterial switch** is performed in the same operation to restore anatomic ventriculoarterial concordance. The double switch operation may necessitate a period of "training" of the left ventricle by means of pulmonary artery banding. The results of this operation are generally less favorable in older patients in whom the right ventricle has been the systemic ventricle for a more prolonged period. The intermediate-term results of this procedure are encouraging, but data for long-term results are limited. Those

with a large VSD may undergo atrial baffling with a **Rastelli operation** (see Table 32.1).

c. Adult patients with symptoms of progressive systemic AV valvular insufficiency may need valve repair or replacement. Most centers that have reported results with this procedure have found improved functional status after surgical treatment and acceptable risks. The timing of surgical intervention among patients with less severe symptoms is a topic of debate, but it is agreed that referral should be considered early before irreversible changes in ventricular function occur.

IV. EBSTEIN ANOMALY. This anomaly of the tricuspid valve represents 0.5% of congenital heart defects. The natural history of this lesion varies from early death to nearly normal expected survival, depending on the degree of tricuspid valve involvement and the presence and type of arrhythmias. An increased risk of **sudden death** irrespective of functional class, presumably caused by arrhythmia, has been observed. **Predictors of poor outcome** include earlier **age** at presentation, **cardiomegaly**, severe **RV outflow abnormalities**, and **disproportionate dilation of the right atrium** relative to the other chambers. There is an association with maternal lithium administration, but most cases are sporadic.

A. Anatomy

1. The **tricuspid valve** is morphologically and functionally abnormal. The basic features include adherence of the septal and posterior leaflet to the myocardium, which lowers the functional annulus toward the RV apex. This results in the classic **atrialization** of the right ventricle (Fig. 32.5) and dilation of the true tricuspid annulus. The anterior leaflet usually is not displaced, but is redundant and may be fenestrated and tethered.

2. **Associated structural anomalies** include **a PFO or ASD** (found in ≥ 80%), **VSD, mitral valve prolapse, and pulmonary stenosis**. ccTGA is associated with Ebstein-like anomaly of the tricuspid (systemic) valve.

B. Clinical presentation

1. **Signs and symptoms** are variable.

a. The presence of a severely insufficient valve can be apparent at birth because of right-to-left shunting across a stretched PFO or ASD, resulting in cyanosis. Pulmonary vascular resistance is high in the neonate and worsens cyanosis,

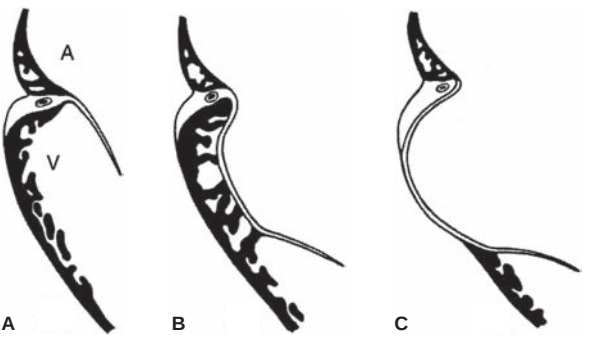

FIGURE 32.5 Section through the right atrioventricular junction. **A:** Normal heart, showing the right atrium (A) and right ventricle (V). **B:** Mild degree of Ebstein anomaly. **C:** Severe Ebstein anomaly. In (**B**) and (**C**), there is apparent displacement of the tricuspid valve. (From Adams FH, Emmanouilides GC, Riemenschneider TA, eds. *Moss' Heart Disease in Infants, Children, and Adolescents.* 4th ed. Baltimore, MD: Williams & Wilkins, 1989, with permission.)

but as pulmonary vascular resistance falls, cyanosis may resolve. In adulthood, as tricuspid regurgitation becomes longstanding with associated decreased RV compliance, cyanosis can reappear. In subtle cases, the anomaly may not be evident until adulthood and then results in nonspecific fatigue, shortness of breath, palpitations, near-syncope, or syncope. In the presence of an interatrial communication, patients may present with paradoxical embolization or brain abscess. Because the spectrum of involvement varies greatly, a high index of suspicion must be maintained.

b. The downward displaced septal leaflet creates a substrate for **accessory pathways**, and clinical Wolff-Parkinson-White syndrome is found in 10% to 25% of patients. Arrhythmias include supraventricular tachycardia mediated by an accessory pathway or caused by atrial arrhythmias from progressive atrial dilation. The combination of atrial fibrillation or flutter conducted rapidly across an accessory pathway is often poorly tolerated.

2. Physical examination

a. General inspection usually reveals normal jugular venous pulsations despite severe tricuspid regurgitation, which is masked by a large compliant atrium. Cyanosis may be present as a result of right-to-left shunting at the atrial level. Digital clubbing will vary depending on the amount of cyanosis.

b. The most common auscultatory findings are the regurgitant murmur of tricuspid insufficiency, gallop rhythms, multiple systolic ejection sounds, and a widely split S_2.

C. Laboratory examination

1. Chest radiography may reveal cardiomegaly, caused by right atrial enlargement from tricuspid insufficiency. Typically, it is described as a globe-shaped heart with a narrow waist.

2. The **electrocardiogram** can demonstrate PR prolongation, right atrial enlargement ("Himalayan" P waves), and superior axis with or without right bundle branch block (Fig. 32.6). The QRS amplitude is characteristically low over the right precordial leads due to a diminutive right ventricle. The preexcitation pattern, if present, is almost always type B (i.e., left bundle branch pattern). Deep Q waves may be seen in leads II, III, and aVF from fibrotic thinning of the RV free wall and/or septal fibrosis.

D. Diagnostic evaluation

1. The diagnosis can be confirmed with transthoracic or transesophageal **echocardiography**, with the tricuspid valve readily visualized in the parasternal short-axis, apical four-chamber, and subcostal views.

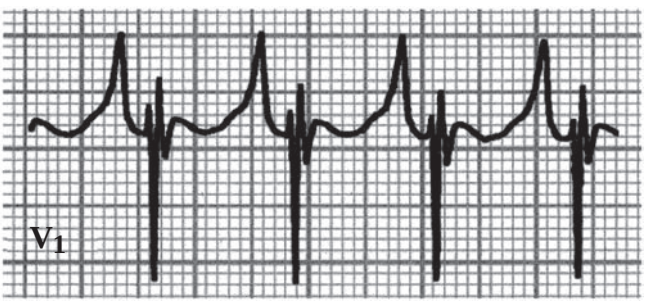

FIGURE 32.6 Lead V_1 of an electrocardiogram from a newborn infant with Ebstein anomaly demonstrates marked right atrial enlargement and an rSR′ pattern.

a. **Apical displacement of the septal leaflet** from the insertion of the anterior mitral valve leaflet by at least 8 mm/m^2 body surface area is considered diagnostic. In less obvious cases, only tethering of the septal leaflet may be found, defined as at least three accessory attachments of the leaflet to the ventricular wall causing restricted motion. An imperforate valve may rarely occur.
b. The **anterior leaflet** may produce functional obstruction of the pulmonary outflow tract. The leaflet in this circumstance is often called "sail-like." The pulmonary outflow is carefully studied to discern functional obstruction from such a leaflet rather than true anatomic atresia of pulmonary outflow.
c. Views of the **atrial septum** are included in all studies to assess the size of the ASD and degree of shunting, if present.
d. The size of the **right ventricle** and true tricuspid annulus is assessed because size guides the feasibility of surgical intervention.
e. The size and function of the **left ventricle** are assessed. The shape of the left ventricle may be unusual because of extreme leftward bowing of the ventricular septum. Left ventricular function can be affected, and abnormalities may affect long-term outcome.
f. **Associated lesions** must be excluded, such as ASD, RV outflow tract obstruction, patent ductus arteriosus, and, in rare instances, mitral valve abnormalities with associated insufficiency.

2. **Cardiac catheterization is unnecessary** for the diagnostic evaluation of Ebstein anomaly, except to exclude coronary artery disease in adult patients with risk factors for whom surgical intervention is planned. Increased risk of cardiac arrest during catheterization has been reported. A diagnostic right heart study may be indicated in the presence of associated hemodynamic abnormalities as part of preoperative planning.
3. Formal **electrophysiologic study** may be considered for patients with arrhythmias or for those being considered for surgical treatment. Radiofrequency ablation of accessory pathways is performed.

E. Therapy

1. A large number of adult patients may undergo **medical treatment**, which includes standard heart failure medications such as diuretics and digoxin. There are no good data to support ACE inhibitors in right heart failure due to Ebstein anomaly. Particular attention must be focused on the management of atrial dysrhythmias, which become more common with age. Permanent pacemaker therapy is required in 3.7% of patients, mostly for AV block and rarely for sinus node dysfunction. Endocarditis prophylaxis is no longer recommended for these patients unless they are cyanotic and unrepaired, have undergone placement of prosthetic material within the preceding 6 months (i.e., ASD occluder device), have a leak adjacent to or at the site of prosthetic material, or have had tricuspid valve replacement.
2. **Surgical correction** usually is recommended for patients with NYHA functional class III–IV symptoms despite medical therapy. The tricuspid valve may be repaired primarily or complete replacement may be necessary, and an interatrial communication, if present, is closed. Patients with symptomatic cardiomegaly, cyanosis, or arrhythmias are considered for surgical intervention. Favorable results have been achieved at centers experienced in the care of adult patients, and functional class has improved after therapy.
3. **Transcatheter closure** of an interatrial shunt can be considered in select patients with cyanosis at rest (oxygen saturation < 90%). Patient selection must be carefully evaluated, as closure of an ASD or PFO may lead to worsening RV dysfunction due to increased right-sided heart pressures. In the case of paradoxical embolic events (i.e., stroke), ASD/PFO closure is considered.

V. EISENMENGER SYNDROME. Eisenmenger syndrome is the clinical phenotype of an **extreme form of pulmonary arterial hypertension associated with congenital heart disease**. Over the last few decades, rapid advances in the modalities of diagnosis and treatment of congenital heart disease have resulted in the ability to repair defects at a much younger age. Pulmonary vascular injury is prevented in many of these children. However, Eisenmenger syndrome is still seen in older patients and occasionally in younger patients, particularly in those from developing countries where access to care may be limited. The natural history of Eisenmenger syndrome is variable; and although a cause of significant morbidity, many Eisenmenger patients survive 30 years or more after the onset of the syndrome.

A. Physiology. Patients with a systemic-to-pulmonary circulation connection will initially have left-to-right shunting of blood due to the lower pulmonary vascular resistance compared with systemic vascular resistance. Over time, because of excessive flow to the pulmonary vasculature resulting in increased shear and circumferential stress, pulmonary vascular resistance increases. Eventually, the shunt reverses, creating right-to-left flow. Although the classic form of the disease was initially used to describe the long-term consequences of a VSD, it can occur with any congenital defect with an initial left-to-right shunt including ASD, AV canal defect, patent ductus arteriosus, aortopulmonary window, and surgically created systemic-to-pulmonary artery shunts. It is important to note, however, that the **physiology and clinical presentation differ depending on the *level* of shunt**. In contrast to patients with nonrestrictive shunts at the ventricular or arterial level, most patients with ASDs do not develop Eisenmenger syndrome, and if they do, they present much later in life. In this case, atrial-level shunting is determined by the compliance of the ventricles and not due to systemic or supra-systemic pulmonary artery pressures.

B. Clinical presentation of Eisenmenger syndrome has multi-organ involvement

1. **Symptoms.** Pulmonary congestion (from the left-to-right shunt) in early childhood may be evident from the history, but improves as the shunt reverses with ensuing cyanosis. Exercise intolerance is very common. Hypoxemia can lead to erythrocytosis and symptoms of hyperviscosity (e.g., headache, dizziness, fatigue, and cerebrovascular accidents). These patients can have a bleeding diathesis due to thrombocytopenia and inadequate clotting factors. This can complicate the management of intrapulmonary thrombosis, which occurs in up to one-third of patients. Hemoptysis is a common symptom—alone or due to pulmonary infarction. Infectious complications include bacterial endocarditis and septic cerebral emboli. Atrial arrhythmias and symptoms of congestive heart failure are usually a late sign and are associated with an increased risk of sudden cardiac death.
2. **Physical examination.** The initial murmur of the associated lesion goes away with reversal of the shunt. Cyanosis and digital clubbing are present, and arterial pulses may be diminished. The cardiac examination reveals signs of elevated right heart pressure, such as jugular venous distention with a prominent *v* wave, a right parasternal heave, a loud pulmonary component of S_2 (sometimes palpable), a right-sided S_4, a holosystolic murmur of tricuspid regurgitation, and a diastolic decrescendo murmur of pulmonary regurgitation. Signs of congestive heart failure such as peripheral edema, ascites, and hepatosplenomegaly are seen later in the disease course.

C. Laboratory examination

1. **Chest radiography** is variable. It may show dilated, even calcified, central pulmonary arteries. Reduced peripheral lung markings are not commonly seen. Patients with ASDs tend to have cardiomegaly due to RV enlargement.
2. The **electrocardiogram** shows evidence of right atrial enlargement and RV hypertrophy. The presence of atrial arrhythmias should be investigated, particularly in the presence of palpitations.

D. Diagnostic evaluation

1. **Echocardiography.** Two-dimensional echocardiography helps in the detailed assessment of the level of the defect, associated lesions, and ventricular function. Doppler measurements can demonstrate and assess the size of the shunt as well as RV pressure and volume overload.
2. **Cardiac catheterization.** Cardiac catheterization is often necessary in these patients to assess the pulmonary vascular resistance. Demonstration of pulmonary vasoreactivity to oxygen, nitric oxide, or other pulmonary vasodilators is prognostic for these patients and can help identify which patients will most benefit from advanced therapies for pulmonary arterial hypertension.

E. Therapy

1. **Medical management**
   a. Chronic nocturnal oxygen therapy has not been shown to be beneficial, although it may improve symptoms in some patients. Anticoagulation is controversial because it can also predispose to hemorrhage or hemoptysis, but it is helpful in preventing thromboembolic events. Hyperviscosity can be managed in ***symptomatic*** patients by performing phlebotomy with isovolumic replenishment, but **routine phlebotomy is contraindicated** due to its effect on iron stores, oxygen-carrying capacity, and increased risk of stroke. Monitoring of iron levels and iron replacement, therefore, is paramount. The management of right-sided heart failure is problematic and the use of digoxin in these patients is controversial. Diuretics should be used cautiously because aggressive diuresis predisposes to hyperviscosity and decreases preload. Endocarditis prophylaxis is warranted.
   b. Over the last few years, there has been a paradigm shift regarding the treatment of pulmonary hypertension in Eisenmenger syndrome. While traditional therapy focused on preventive and palliative measures, there is accruing evidence to suggest that the **disease is in fact modifiable and that selective pulmonary vasodilators are not only safe but likely beneficial** in this population. These agents include endothelin antagonists, prostacyclin analogs, and phosphodiesterase-5 inhibitors. The only randomized, placebo-controlled trial performed to date in Eisenmenger patients, BREATHE-5, showed reduction in pulmonary vascular resistance and improvement in exercise capacity (with no detriment to oxygen saturation) using bosentan (an endothelin antagonist). In general, intravenous treatments are avoided in this population due to the risk of paradoxical embolism and increased infectious risk with indwelling lines.
2. **Surgical management.** Selected patients may be candidates for combined heart–lung transplantation or lung transplantation with concomitant repair of the intracardiac defect, if feasible. Timing of these interventions may be difficult because of the relatively long-term survival of these patients after the onset of the disease process and the recent availability of selective pulmonary vasoactive therapy.

F. Eisenmenger syndrome in special situations

1. **Travel** to areas of high altitude should be avoided because it may result in acute right heart failure. Air travel, however, is not contraindicated, as cabin pressures during commercial flights are generally well-tolerated.
2. **Pregnancy** in these patients is high risk to the fetus and the mother (> 50% maternal mortality) and is generally contraindicated. Given the high risk of maternal and fetal mortality, contraceptive methods (preferably without the use of estrogen) are critical. Elective termination should be discussed with pregnant Eisenmenger patients.
3. **Noncardiac surgery** is also associated with high risk and should be performed under the supervision of anesthesiologists familiar with Eisenmenger syndrome.

Syncope

I. INTRODUCTION

A. Syncope is a common medical problem that accounts for approximately 6% of medical admissions and 3% of emergency room visits. Syncope is defined as a **sudden transient loss of consciousness with associated loss of postural tone. Recovery is spontaneous, without neurologic deficit and without requiring electrical or chemical cardioversion.** Generally, a fall in systolic blood pressure below 70 mm Hg or a mean arterial pressure of 40 mm Hg results in loss of consciousness. Cerebral blood flow usually decreases with aging, making the elderly at higher risk for syncope.

B. Syncope as a symptom can be caused by a **variety of medical diseases that produce a transient interruption of cerebral blood flow**.

1. A genuine effort should be made to **determine a specific cause of syncope**. Identifying a specific cause can help in the selection of therapy, prevent recurrences, minimize expensive evaluations, and decrease morbidity.
2. **Patients with cardiac syncope have higher rates of mortality and sudden death** at follow-up. Identifying and treating cardiac syncope can improve outcome.

II. CLINICAL PRESENTATION.

Although a variety of diagnostic tests are available for evaluation of syncope, a thorough history and physical examination are crucial to determine the cause and the best diagnostic approach. A good history and physical examination can provide a clue to the diagnosis in up to 50% of cases.

A. Signs and symptoms. Accurately described symptoms can lead to specific diagnostic considerations, as illustrated in Tables 33.1 and 33.2. Table 33.3 lists the prevalence of various causes of syncope as seen in the Evaluation of Guidelines in Syncope Study 2 (EGSYS-2) trial, a prospective systemic evaluation of consecutive patients referred to various emergency rooms for syncope.

1. **The most** important aspect of history taking is to **determine the circumstances before syncope (i.e., the prodrome)**; whether there is association with any particular activity, exertion, or change in position; and the frequency of occurrence.
2. The initial approach to any patient with syncope should include a **search for the presence of structural heart disease such as valvular stenosis, cardiomyopathy, or myocardial infarction**. The presence of any of these may suggest more malignant causes such as ventricular tachycardia.
3. **Symptoms of vasovagal syncope.** Calkins et al. (1) reported that a careful history could diagnose vasovagal syncope. They reported that **women (< 55 years) with a postsyncopal recovery period that included fatigue** and patients with **clear precipitating factors, diaphoresis, palpitations preceding syncope, and severe fatigue after syncope** were more likely to have vasovagal syncope than ventricular tachycardia or complete heart block.
4. **Convulsive syncope.** Occasionally, a syncopal episode is accompanied by **mild muscular jerking** as a result of cerebral anoxia. This phenomenon is not true epilepsy, and the physician must make every effort to distinguish between

syncope and a seizure. Syncope typically occurs without an aura and has a more deliberate onset. Seizures are characterized by severe jerking motions, longer periods of unconsciousness, and severe fatigue after the event (i.e., postictal state). Seizures may occur without regard to patient positioning. In contrast, syncope rarely happens when a person is recumbent.

5. Other entities that make diagnosis difficult are **vertigo, transient ischemic events, somatization disorders (e.g., conversion and hysteria), cataplexy, epilepsy, and drop attacks**.

TABLE 33.2 Clinical Features Suggesting Specific Causes

Symptoms or finding	Diagnostic consideration
After sudden unexpected pain, unpleasant sight, sound, or smell	Vasovagal syncope
During or immediately after micturition, cough, swallow, or defecation	Situational syncope
With neuralgia (glossopharyngeal or trigeminal)	Bradycardia or vasodepressor
Upon standing	Orthostatic hypotension
Taking hypotensive medication	Drug-induced syncope
Symptoms within 1 h after meals	Postprandial hypertension
Prolonged standing at attention	Vasovagal
Well-trained athlete after exertion	Vasovagal
Changing position (from sitting to lying, bending, turning over in bed)	Atrial myxoma, thrombus
Syncope with exertion	Aortic stenosis, pulmonary hypertension, mitral stenosis, HOCM, coronary artery disease
With head rotation, pressure on carotid sinus	Carotid sinus syncope
Associated with vertigo, dysarthria, diplopia	TIA, stroke
With arm exercise	Subclavian steal syndrome

HOCM, hypertrophic obstructive cardiomyopathy; TIA, transient ischemic attack.

Adapted from Kapoor WN, Smith M, Miller NL. Upright tilt testing in evaluating syncope: a comprehensive literature review. *Am J Med.* 1994;97:78–88.

6. The examiner should always **carefully review the medications of a patient with syncope** for their potential role, directly or by interaction with other medications.

B. Physical findings

1. The **physical examination is especially important when the patient is unable to describe the event** and no witnesses are available, as certain findings on examination can direct the physician in the diagnostic evaluation.
2. The **comprehensive evaluation** should include a funduscopic examination of the eye for evidence of embolism. The evaluation should also search for the presence of carotid bruit and assessment of the carotid upstroke; subtle neurologic deficits that may result from a stroke or neuropathy; cardiac murmurs with attention given to valvular findings and extra heart sounds (such as tumor plop); peripheral pulses for evidence of peripheral vascular disease and entities such as subclavian steal; and dermatologic clues that may suggest collagen vascular disease or vasculitis.
3. In examining a patient with syncope, it is important to check **blood pressure in both arms as well as orthostatic blood pressure**. Repeated orthostatic blood pressure measurements may be needed when there is a high level of clinical suspicion for orthostatic syncope (see Section **II.C.1.c**).
4. Syncope in the absence of underlying heart disease is not associated with increased mortality. The morbidity of such episodes is related to harm that may occur in association with a syncopal event.

C. Etiology and pathophysiology

1. **Neurally mediated syncope.** Vasovagal or neurally mediated syncope is the **most common cause of syncope**. Many situations can lead to vasovagal "fainting." Examples include unpleasant smell, sudden pain, acute blood loss, and sustained upright posture. Vasovagal reactions are often preceded by an increase in heart rate and blood pressure.
   a. **Neurocardiogenic syncope** is thought to be the result of **autonomic overactivity followed by a fall in peripheral vascular resistance, without a significant rise in cardiac output**. In susceptible individuals, the stimulation of mechanoreceptors located in the inferior and posterior wall of the left ventricle by stretch, cardiac distention, or rapid systolic contraction leads to increased neural discharges through unmyelinated C fibers to the vasomotor center in the medulla, resulting in enhanced parasympathetic and decreased sympathetic activities. The withdrawal of the sympathetic nervous system results in sudden bradycardia or hypotension. Animal studies suggest that cardiac afferents may not be required to initiate a vasodepressor response and that other potential mechanisms, such as release of endogenous opioids or nitric oxide inhibition of sympathetic nerve firing and primary central nervous system activation, may play a role in vasodepressor syncope.
   b. **Situational syncope.** Patients often recall situational syncopal episodes. **Micturition, defecation, cough, and trumpet playing** are examples. The action causes a reflex vasodilation (vagally mediated) that is exacerbated if the patient performs a Valsalva maneuver, which decreases the blood return to the right heart.
   c. **Orthostatic syncope. Postural hypotension** is reported in up to 24% of elderly people. Normally when a person stands, the systolic blood pressure drops only 5 to 15 mm Hg, and the diastolic pressure rises slightly. In orthostasis, the decrease in systolic blood pressure exceeds 20 mm Hg; frequently, the diastolic pressure drops by > 10 mm Hg. This finding demands a search for a potential cause.
      (1) Common causes include **volume depletion, medications, diabetes, alcohol, infection, and varicose veins**.

(2) **Dysautonomic syndromes** causing orthostatic hypotension are divided into two categories: primary and secondary. Primary autonomic failure is idiopathic and includes pure autonomic failure (i.e., Bradbury-Eggleston syndrome) and multisystem atrophy (i.e., Shy-Drager syndrome). Secondary causes include amyloidosis, tabes dorsalis, multiple sclerosis, spinal tumors, and familial dysautonomia.

a. **Carotid sinus syncope.** Less than 1% of patients presenting with syncope have been given a diagnosis of carotid sinus syncope. This entity should be considered in patients with spontaneous symptoms while shaving, swimming, turning the head, or wearing a tight collar, as well as in older patients with recurrent syncope. A cardioinhibitory response (i.e., bradycardia) occurs in about 70%, and a vasodepressor response (i.e., hypotension) occurs in 10%. The remaining patients have a mixed response (i.e., bradycardia with hypotension). Carotid sinus syncope is elicited by manual pressure on the carotid sinus and can be blocked by atropine. Clinical presentation along with findings of carotid sinus hypersensitivity in the absence of other potential causes is enough to make the diagnosis. Symptom reproduction during carotid massage is not necessary for a diagnosis. A positive carotid test result is defined by cardiac asystole of 3 seconds or longer, a drop in systolic blood pressure of > 50 mm Hg, or a drop of > 30 mm Hg in blood pressure and symptoms. Carotid massage should be avoided in patients with a history of stroke or transient ischemic attack (TIA) within 3 months (unless they have had normal carotid Doppler results) or those patients in whom carotid bruits are heard on clinical examination.

2. **Cardiac syncope**

a. **Mechanical causes**

(1) Syncope or related symptoms frequently occur with exertion and arise from left ventricular outflow obstruction, as seen in aortic stenosis or hypertrophic obstructive cardiomyopathy (HOCM). With exertion, peripheral vascular resistance falls, but the cardiac output is fixed, leading to hypotension. Arrhythmias and altered baroreceptor response also play a role in syncope in patients with an obvious mechanical cause, such as aortic stenosis.

(2) **Right ventricular outflow obstruction** can also result in syncope. This condition can also trigger a vasodepressor component by mechanisms similar to neurocardiogenic syncope.

(3) **Myocardial ischemia and infarction, pulmonary embolus, and cardiac tamponade** should be kept in mind. **Syncope may be the initial complaint in 7% of patients older than 65 years presenting with myocardial infarction**.

(4) **Patients with hypertrophic obstructive cardiomyopathy** have an annual risk of sudden death in nonselective populations of approximately 1% per year. Syncope increases the relative risk of sudden cardiac death by approximately fivefold. The presence or absence of other sudden death risk factors (family history of sudden cardiac death, nonsustained ventricular tachycardia, marked left ventricular hypertrophy, and significant left ventricular outflow tract gradient) influences the risk of sudden cardiac death. Electrophysiologic (EP) testing plays a minimal role in risk stratification, as does genotyping for specific mutations currently. Treatment in high-risk patients usually includes the use of β-blockers, calcium channel blockers, disopyramide and other antiarrhythmics, and frequently implantable cardioverter–defibrillator (ICD) placement.

(5) **Arrhythmogenic right ventricular dysplasia** is a disorder in which syncope is caused by ventricular tachycardia originating in the right ventricle secondary to replacement of myocardium by adipose tissue

and/or fibrosis. The imaging modality of choice is cardiac magnetic resonance imaging (usually with fat suppression), which usually shows thinning, aneurysms, and replacement of right ventricular myocardium with adipose and fibrotic tissues. It is thought to be a common cause of sudden cardiac death in patients younger than 35 years and may be familial in 30% to 50% of patients. It is usually diagnosed based upon the presenting electrocardiogram (ECG), suggested by the presence of premature ventricular contractions or sustained ventricular tachycardia with a left bundle branch morphology. Treatment of syncope in this setting usually includes ICD implantation, and yearly ICD appropriate therapy rates are usually 15% to 20%.

(6) Ion Channel disorders

(i) Long QT syndrome. This is characterized by prolongation of the QT interval, with a measured QTc > 450 milliseconds. The long QT syndromes are actually a heterogeneous group of disorders and have been mapped to genetic defects in either cardiac potassium channels (LQT1 and LQT2) or sodium channels (LQT3). It is worthwhile mentioning that the potassium channel mutations involve a loss of function of the potassium channels, whereas sodium channel mutations involve a partial gain of function. The lifetime risk of syncope or sudden cardiac death increases with increasing QTc, reaching 50% for QTc > 500 milliseconds. Syncope is usually the result of an episode of torsade de pointes or self–terminating polymorphic ventricular tachycardia and is an ominous finding. Treatment options include β-blockers and ICD implantation, as well as lifestyle modifications, including the restriction of strenuous or competitive exercise and avoidance of QT-prolonging drugs.

(ii) Brugada syndrome is a disorder of cardiac sodium channels that results in transient downsloping ST elevations in the anterior precordial leads and leads to a susceptibility to polymorphic ventricular tachycardia. Patients with Brugada syndrome with syncope have a 2-year risk of sudden cardiac death of approximately 30%; therefore, treatment with an implantable defibrillator is recommended.

b. Electrical causes. Ventricular tachycardia, sick sinus syndrome, and atrioventricular block are the most common causes of syncope related to arrhythmias. One must also consider supraventricular tachycardia, Wolff-Parkinson-White syndrome, and torsade de pointes. Arrhythmic syncope carries the worst prognosis and must be thoroughly evaluated.

(1) Primary cardiac arrhythmias are the most common cause of syncope in patients with known cardiac disease, such as previous myocardial infarction, left ventricular dysfunction, or cardiomyopathy.

(2) Medications that prolong the QT interval and electrolyte abnormalities should also be considered as causes of arrhythmic syncope.

(3) Patients with pacemakers should have their pacemaker interrogated for possible malfunction. The possible causes include battery depletion, lead malfunction, or lead dislodgment. Individuals with pacemaker or implantable defibrillators should be educated about the devices and examined regularly. An observed phenomenon in patients with atrial fibrillation who undergo atrioventricular nodal ablation (and are subsequently pacemaker dependent) is the development of syncope secondary to ventricular tachycardia, presumably because of an R on T phenomenon. Because of this, such patients are usually programmed with a higher backup rate (at least 90 beats per minute) for the 4 to 6 weeks following atrioventricular nodal ablation.

3. **Noncardiovascular syncope**
   a. **Neurologic causes** include stroke, TIAs, normal pressure hydrocephalus, and seizures. Other causes include orthostatic hypotension from dysautonomia, and this diagnosis should be suggested based on history, screening neurologic examination, and orthostatic vital signs.
   b. **Metabolic causes** include arrhythmias induced by hypoglycemia, hypoxia, and hypokalemia.
   c. **Psychogenic causes** include anxiety disorder, panic disorder, hyperventilation, somatization, depression, hysterical syncope (i.e., no change in blood pressure or pulse), and conversion disorder.
   d. Drugs that can cause syncope include **nitrates, angiotensin-converting enzyme inhibitors, calcium channel blockers, β-blockers, quinidine, procainamide, disopyramide, flecainide, amiodarone, diuretics, vincristine, insulin, cocaine, and digoxin. The α-blockers** (e.g., prazosin) are potent agents and commonly cause orthostatic hypotension, especially in the elderly. These agents should be initiated with careful instructions to the patient regarding orthostasis and should be prescribed to be taken in the evening. Orthostatic hypotension can be induced by tricyclic antidepressants or antiparkinsonian agents as well.
4. **Unknown or unexplained causes.** Past studies indicated that 33% to 50% of patients with syncope had no identifiable cause. One study showed that these patients are still at a higher risk for subsequent death from any cause, with a multivariable-adjusted hazard ratio of death of 1.32 (95% confidence interval: 1.09 to 1.60). Other diagnostic tools such as tilt table testing, loop recorders, signal-averaged electrocardiography (SAECG), and EP studies may assist physicians in identifying a previously unknown cause of syncope.

   Stress testing, electroencephalography, computed tomography of the head, and cerebral angiography have a very low yield unless there is a history of trauma, stroke, or seizures.

III. DIAGNOSTIC TESTING. A single ECG offers the possible diagnosis in approximately 5% of cases. It can demonstrate sinus pause, high-degree atrioventricular block, prolonged QT interval, or Wolff-Parkinson-White syndrome. Echocardiography, Holter monitoring, loop recorders, SAECG, EP testing, and tilt table testing are major diagnostic tools. Their yield depends on the presence or absence of underlying structural heart disease.

A. In evaluating a patient with syncope, **it is important to differentiate patients with and without structural heart disease**. The goal of evaluation should be to obtain a correlation between symptoms and an abnormal finding during diagnostic testing. There are several key points:
1. Cardiac syncope carries a high mortality rate, and physicians should **admit any individual suspected of having cardiac syncope** for evaluation.
2. **Syncope in the elderly** is frequently multifactorial (e.g., drugs, structural heart disease, anemia, volume depletion, and decreased baroreceptor sensitivity).
3. The **workup should be individualized** to be cost-effective and accurate, as shown in Figure 33.1.

B. **Echocardiography** is routinely used for diagnosing patients with syncope who are suspected of having cardiac disease. The echocardiogram is useful in diagnosing valve pathology and myocardial processes that may contribute to syncope, such as aortic stenosis and cardiac tumors (i.e., myxomas). Some small studies and case reports suggest that echocardiographic data frequently aid in diagnosing a cardiac origin for syncope. However, larger studies have shown that the diagnostic yield of echocardiography is quite low in the absence of clinical, physical, or electrocardiographic findings, suggesting a cardiac abnormality. In patients with syncope or presyncope and a normal physical examination, mitral valve prolapse is the most common finding.

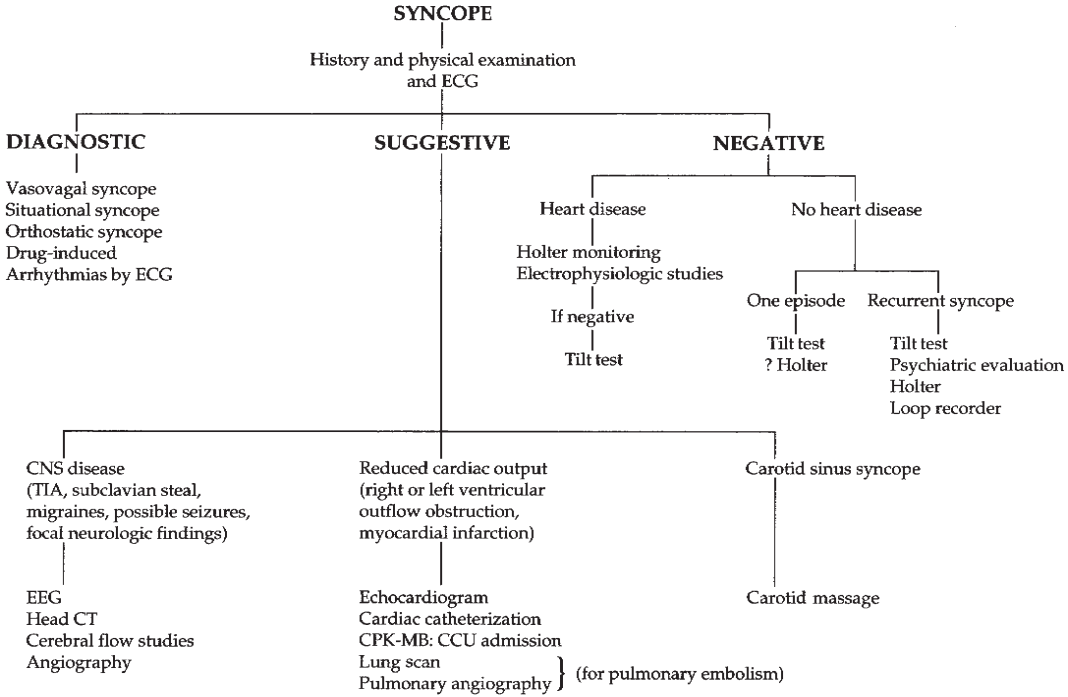

FIGURE 33.1 Schematic algorithm for the evaluation of patients presenting with syncope. ECG, electrocardiogram; CNS, central nervous system; TIA, transient ischemic attack; EEG, electroencephalogram; CT, computed tomography; CPK-MB, creatine phosphokinase-myocardial band; CCU, coronary care unit. (From Kapoor WN. Diagnostic evaluation of syncope. *Am J Med.* 1991;90:91–106, with permission.)

C. Holter monitoring. Holter or prolonged electrocardiographic monitoring is one of the most commonly used tests for the evaluation of syncope. However, symptomatic correlation of a cardiac arrhythmia with a syncopal spell occurs in only about 4% of cases. **A completely normal or negative Holter result may be just as helpful as a captured arrhythmia**. The sensitivity and specificity of electrocardiographic monitoring for arrhythmic syncope are not known because of the lack of criteria for abnormal results or a gold standard that is independent of arrhythmias diagnosed by monitoring. The difficulty is to establish a correlation between arrhythmia and asyncopal spell.

1. Gibson et al. reviewed 1,512 Holter recordings of patients referred for evaluation of syncope; a total of 255 (17%) patients reported syncope or related symptoms, of which only 30 (2%) were correlated with arrhythmias. Ventricular tachycardia was predominant in the syncope group, whereas supraventricular and sinus tachycardia were common in the presyncope group. There was an increasing incidence of supraventricular and ventricular tachycardia with age, but the correlation with syncope remained obscure.
2. Pratt et al. studied 80 patients with structural heart disease were investigated by Holter monitors and follow-up EP study. The authors concluded that the combination of a clinical presentation of syncope, presence of coronary artery disease, and left ventricular ejection fraction < 30% had a better positive predictive value in terms of inducibility of sustained ventricular tachycardia than any ambulatory electrocardiographic monitoring criteria.
3. Studies have shown that **sinus pauses longer than 2 seconds, second-degree atrioventricular block (type II) or complete atrioventricular block, and runs of nonsustained ventricular tachycardia on Holter monitoring should be taken seriously**.
4. The duration of electrocardiographic monitoring is an important issue. It appears that **48 hours is optimal**.

D. Loop recorder. When used correctly, **loop recorders effectively couple arrhythmias and syncope**. Loop recorders are **useful in patients with recurrent frequent syncope**, who benefit from prolonged monitoring for weeks to months. When activated by the patient, loop recorders permanently record the previous 4 to 5 minutes of rhythm data. The recorder can capture arrhythmias during a syncopal episode if the patient activates it after regaining consciousness. The next-generation loop recorders (e.g., Medtronic-Reveal) are implantable devices similar to a pacemaker. They continuously record a single-lead ECG. These devices have the capability to store a 15-minute segment of cardiac rhythm when activated during or after a syncopal episode by the patient and can also be programmed to automatically begin recording when triggered by a high or low heart rate.

Two randomized clinical trials have shown that implantable loop recorders (ILRs) are more likely to lead to a diagnosis of syncope than conventional management. In the Randomized Assessment of Syncope Trial (RAST), 60 patients were randomized to receive either an ILR or conventional testing. A diagnosis was made in 52% of the patients with an ILR and in only 20% of the patients receiving conventional testing ($p = 0.012$). In the Eastbourne Syncope Assessment Study (EaSyAS), 201 patients were randomized to receive an ILR or conventional diagnostic testing. An ECG diagnosis of syncope was established in 33% of the patients with ILR but in only 4% of the conventional strategy patients ($p < 0.0001$).

E. SAECG is useful in predicting inducibility of ventricular arrhythmias by EP testing, especially in patients with ischemic heart disease. However, it is not helpful in diagnosing sinus pauses or atrioventricular block. Most patients with syncope in the setting of structural heart disease are likely to require an EP study or implantation of a defibrillator if left ventricular dysfunction or coronary artery disease is present. SAECG may, therefore, be more appropriately employed in patients with

structurally normal hearts to predict whether an EP study is indicated. SAECG may also be helpful in identifying patients with arrhythmogenic right ventricular dysplasia or infiltrative cardiomyopathies.

1. **SAECG** is a collection of 100 to 300 single QRS complexes, which are amplified, filtered for noise, and averaged to determine the presence of late potentials. Late potential refers to the presence of low-amplitude, high-frequency signals in the terminal segment of the amplified QRS. **The late potentials seem to identify the presence of a reentrant substrate and may indicate an independent risk for the development of future life-threatening ventricular arrhythmias**.
2. **When combined with an ejection fraction of < 40%, the presence of late potentials can be used to identify patients with an even higher risk of ventricular tachycardia**. Studies evaluating this profile of patients have demonstrated sensitivity of 90% and specificity of 95% to 100% in predicting inducible, sustained ventricular tachycardia.
3. Various commercially available devices use different filters, lead configurations, and processing algorithms; therefore, the **criteria for abnormal SAECG may vary among manufacturers**. Abnormal SAECG findings include total QRS duration > 114 milliseconds, root mean square voltage of the terminal 40 milliseconds of the complex (RMS40) < 20 μV, or duration of low-amplitude signals (LASs) in terminal QRS (LAS) > 38 milliseconds. The total duration of the QRS complex, including the late potential, is independent of other measures of cardiac risk. RMS40 is probably the most sensitive and specific of all three variables.
4. **A positive SAECG finding suggests the need for further EP testing**, especially in individuals with known heart disease.
5. The **absence of late potentials has a high negative predictive value (94%)**. In patients with syncope and a negative SAECG result, EP study is not absolutely indicated. A normal SAECG result is associated with a < 5% risk of inducible ventricular tachycardia on EP testing.
6. **No satisfactory method of analysis is available for patients with bundle branch block**, because it is virtually impossible to distinguish between late activation due to the conduction defect and that due to the reentrant substrate.

F. EP study. EP study should be considered in **patients with underlying structural heart disease or in elderly patients with recurrent syncope**. Similar to Holter monitoring, induced arrhythmias during EP study do not usually produce syncope in the laboratory; therefore, a cause-and-effect relationship often has to be assumed. Regardless, EP testing is useful in better delineating a cardiac cause of syncope, especially in people with baseline bundle branch or bifascicular block.

1. **Indications** for EP study generally include the following:
   - **(a)** Known or suspected ventricular tachyarrhythmias, especially to guide therapy
   - **(b)** Uncertainty about the origin of wide QRS tachycardia
   - **(c)** Patients with unexplained syncope and history of heart disease
   - **(d)** Patients with nonsustained ventricular tachycardia, impaired left ventricular function, and late potentials on SAECG, used to stratify prognosis and guide therapy
   - **(e)** Patients with drug-refractory malignant ventricular arrhythmias who are candidates for ablative therapy
2. Some **EP findings** are considered important in the cause of syncope:
   - **(a)** Sustained monomorphic ventricular tachycardia
   - **(b)** Sinus node recovery time longer than 3 seconds
   - **(c)** Spontaneous or pacing-induced infranodal block or infrahisian block
   - **(d)** Baseline His-ventricle (HV) interval > 100 milliseconds or significant prolongation after procainamide challenge
   - **(e)** Paroxysmal supraventricular tachycardia with symptomatic hypotension

3. The sensitivity and specificity of induced, sustained monomorphic ventricular tachycardia are > 90%. However, the sensitivity of prolonged sinus node recovery time is low (69%), although the specificity is reported to be as high as 100% when EP studies are compared with results of Holter monitoring.
4. Patients with no known heart disease, ejection fraction > 40%, normal electrocardiographic and Holter results, and multiple syncopal episodes (more than five per year) often have **negative EP study results**. A 3-year follow-up of patients with negative EP test results revealed a 24% recurrence rate of syncope and a mortality rate of 15%; however, **a 3-year follow-up after positive EP study results and treatment revealed a 32% recurrence rate and higher mortality (61%)**.
5. For patients with coronary artery disease and syncope who have mild to moderate left ventricular dysfunction (left ventricular ejection fraction, 35% to 50%), inducible ventricular tachycardia during an EP study is unlikely, but the study is often appropriate, given the significant implications of a positive test.
6. Patients with stable coronary artery disease and severe left ventricular dysfunction (< 35%) have substantial benefits once treated with an ICD. Hence, an EP study is often not required.
7. Patients with severe nonischemic dilated cardiomyopathy (EF < 40%) and New York Heart Association (NYHA) class II–III symptoms do not benefit from an EP study, and there is no evidence to support the use of antiarrhythmic medications in these patients. Evidence from the Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) supports the mortality benefit from ICD implantation in these patients with heart failure symptoms. Moreover, patients with wide QRS (> 120 milliseconds) and severe cardiomyopathy with NYHA class II–III symptoms benefit symptomatically from cardiac resynchronization therapy (CRT) and have an improvement in mortality compared with antiarrhythmic medications by receiving a CRT-defibrillator device.
8. **The limitations and disadvantages of EP testing** are high cost, invasive nature, lower specificity if a more aggressive electrical stimulation protocol is used, and poor prediction of bradyarrhythmias and several other arrhythmias of unknown clinical significance without symptoms. A detailed discussion of EP studies is provided in Chapter 63.

G. Upright tilt table testing

1. **Mechanism.** It is believed that a surge in catecholamines may paradoxically enhance the susceptibility to bradycardia and hypotension, resulting in syncope by the activation of cardiac mechanoreceptors. Vasovagal syncope can be induced by keeping susceptible individuals upright on a tilt table with or without chemical stimulation. The mechanism is not completely understood, but it is believed to be similar to the activation of the Bezold-Jarisch reflex.
2. The best candidate for a tilt table study is a **person with unexplained recurrent syncope, with underlying heart disease and a negative EP study or with no known structural heart disease**. In reviewing various tilt table studies, Kapoor et al. (2) found that 49% of patients had a positive response during tilt table testing, 66% had a positive response using isoproterenol with tilt table testing, 65% had a cardioinhibitory response, and 30% had a vasodepressor response. The **number of positive responses increased with an increasing angle of tilt and longer duration**; however, there was no correlation between positive responses and maximum dose of isoproterenol. Although limited information is available on the sensitivity of upright tilt table testing, it is reported to be about 70%. The specificity has ranged from 35% to 92% with isoproterenol. Kapoor et al. (2) reported higher false-positive rates with isoproterenol, especially at higher angle of tilt, indicating lower specificity.

3. It appears that **tilt table testing, when used in the appropriate setting, is beneficial in diagnosing previously unexplained syncope**, preventing recurrences, and reducing morbidity.

H. Adenosine triphosphate (ATP) test. The intravenous injection of ATP has been suggested to aid in the diagnosis of unexplained syncope. Patients are injected with a 20-mg bolus of ATP and are kept in a supine position with continuous electrocardiographic monitoring. Asystole lasting more than 6 seconds or atrioventricular block lasting longer than 10 seconds is considered abnormal. In patients with unexplained syncope, the ATP test may be able to diagnose syncope caused by transient atrioventricular block. However, it has not been able to reproduce sinus arrest. This test remains in the investigational phase, and outcome data are not yet available.

IV. TREATMENT.

Treatment of syncope is individualized and depends on the underlying cause.

A. Nonpharmacologic therapy. The treatment of syncope hinges on preventing recurrent episodes and lowering mortality. The neurally mediated reflex syncopal syndromes can be treated in part by behavior modification. Initial measures aimed at reducing these syncopal events include advising patients to avoid precipitating triggers. Patients should also be counseled on the avoidance of volume depletion. Medication regimens such as chronic vasodilator therapy may predispose to syncope and should also be avoided. Moderate exercise training, tilt training, and increased intake of salt and electrolytes are some initial measures that help in reducing vasovagal syncope.

Small trials have shown a benefit from tilt training and counterpressure maneuvers to prevent neurally mediated syncope. In tilt training, patients are subjected to progressively longer periods of upright posture in order to condition the neural and vascular systems to counter gravitational stress. In one small study of 42 patients with neurally mediated syncope, tilt training resolved symptoms in 36 patients during the period of training. Counterpressure maneuvers are isometric arm and leg exercises that patients perform at the first sign of a syncopal episode. These maneuvers raise peripheral vascular resistance and blood pressure and can prevent the syncopal spell. In one trial of 21 patients, patients were trained to perform isometric leg exercises during a tilt table test. The maneuver successfully raised blood pressure and prevented syncope during the tilt table test, and at follow-up in 10 months, 13 of 20 patients continued to use the maneuver in daily life. These treatments are often used as first-line therapy for neurally mediated syncope.

B. Medical therapy. Most long-term, randomized studies testing the utility of using medications to prevent syncope, including those of β-blockers, have failed to show any benefit over placebo, and these treatments are generally considered second line. Table 33.4 lists the various causes of syncope and potential medical treatment.

1. **Electrolyte abnormalities must be corrected** if they are suspected as the cause of arrhythmias (e.g., prolonged QT from hypomagnesemia or hypocalcemia).
2. **Particular attention should be given to the patient's medications**, since they may have drug–drug interactions or proarrhythmic potential that may cause orthostatic hypotension. Unnecessary medications should be discontinued.

C. Device therapy

1. **Symptomatic bradyarrhythmias and atrioventricular blocks require pacemaker implantation**
   a. Patients with an HV interval (i.e., impulse time from atrioventricular node to the ventricle) of > 100 milliseconds are at a high risk for **progression to heart block** and may benefit from a pacemaker.
   b. Although the mode of pacing is debated, in **patients with carotid sinus syncope**, a dual-chamber pacer with rate responsiveness is most desirable.

TABLE 33.4 Medical Therapy in Syncope

Cause	Treatment
Vasodepressor syncope	β-Blockers, disopyramide CR 200 mg bid, fluoxetine 20–80 mg daily, sertraline 50–200 mg daily, dual-chamber pacing, theophylline ER 300–600 mg daily, and scopolamine hydrobromide 0.4–0.8 mg bid–tid
Dysautonomic syncope	Elastic support hose, water exercise, increased sodium intake, fludrocortisones 0.05–0.2 mg daily, ephedrine sulfate 25–50 mg tid, midodrine 5–10 mg tid, erythropoietin, and methylphenidate 5–20 bid–tid
Situational syncope	Stool softeners, urinating while sitting down
Carotid sinus syncope	Avoidance of tight collars, surgical removal of carotid sinus tumor, pacemaker in patients with predominantly cardioinhibitory syncope
Tachyarrhythmias	Implantable defibrillators or trial of antiarrhythmic agents

CR, controlled release; ER, extended release.

Adapted from Kapoor WN, Smith M, Miller NL. Upright tilt testing in evaluating syncope: a comprehensive literature review. *Am J Med.* 1994;97:78–88.

c. Dual-chamber pacing has reduced the short- and long-term likelihood of syncope in highly selected patients with recurrent vasovagal syncope. In patients with recurrent vasovagal syncope, dual pacing with hysteresis should be considered an option if other treatment modalities have been ineffective.

2. **Antiarrhythmic therapy** appears to decrease the frequency of syncope; however, it has not been shown to improve survival. In patients with malignant or life-threatening ventricular arrhythmias or inducible, sustained monomorphic ventricular tachycardia, **implantable defibrillators** are the best option based on study findings, especially in patients with unexplained syncope who have a history of coronary artery disease and severe left ventricular dysfunction.

D. Surgical therapy

1. **Patients who have exertional cardiac syncope** due to left or right heart outflow obstruction, such as HOCM, should be instructed to **avoid exertional activities** that precipitate syncope and **should be considered for surgical repair**.
2. Surgical septal myectomy is the procedure of choice in **patients with HOCM**; however, percutaneous septal ablation with alcohol is an alternative in patients who are considered at high surgical risk.
3. Coronary artery bypass grafting or percutaneous coronary intervention is strongly indicated in **patients with life-threatening arrhythmias (usually polymorphic ventricular tachycardias) due to myocardial ischemia**.

V. FOLLOW-UP. The follow-up of patients with syncope often depends on the cause and the therapy being instituted.

A. Patients with frequent spells of syncope without an identifiable cause should be considered for more extensive monitoring such as ILRs, because they may have an undiagnosed cardiac cause.

B. Patients with cardiac syncope require very close follow-up because their mortality rates are significantly higher than those of patients with other causes of syncope.

C. **Elderly patients** may require closer monitoring about their home situation, their need for assistance with activities of daily living, and changes in medications.

D. A consultant who diagnoses syncope should **communicate with the patient's primary physician about cause, therapy, and important warning signs** if devices such as pacemakers or defibrillators are implanted.

E. **Hospitalization.** The decision about which patients to hospitalize can be complex. The underlying heart disease has been found to be the most important factor in determining prognosis and risk stratification, and it mandates hospitalization for the evaluation of syncope. Patients without evidence of structural heart disease who have a normal ECG and a high probability of having neurally mediated syncope are at low risk and generally have good long-term outcomes. Outpatient evaluation of syncope may be appropriate for these patients in many instances. Physicians should also consider hospitalization for patients with exertional syncope, syncope causing severe injury, and those with a strong family history of sudden death.

Risk scores have been developed to help predict which syncope patients are at risk for a serious outcome and should be considered for hospitalization. One of these, the San Francisco Syncope Rule, can be remembered by the mnemonic CHESS (history of *c*hronic heart failure, *h*ematocrit < 30%, abnormal *E*CG, *s*hortness of breath, *s*ystolic blood pressure < 90 mm Hg). This risk score was derived from a group of 684 syncope patients who presented to the emergency department of a university hospital. Use of this score identified patients at risk of a serious outcome with 96% sensitivity and 62% specificity.

VI. POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME (POTS).

POTS is an emerging and still poorly understood syndrome in which patients feel an exaggerated increase in heart rate with tilt and exercise. They may also feel fatigue, dyspnea, and light-headedness on standing, but do not typically experience orthostatic hypotension or syncope. The disorder is the most common syndrome seen in young people referred to autonomic dysfunction clinics and is thought to affect 500,000 Americans. Patients typically present at age 14 to 45 years and are usually female (female to male ratio of 4 to 5:1). Patients often have multisystem complaints such as fibromyalgia, chronic fatigue syndrome, sleep disorders, and gastrointestinal symptoms, suggesting a diffuse autonomic dysfunction.

A. **Etiology.** POTS is thought to be a syndrome with multiple overlapping etiologies, with each etiology having varying importance in individual patients.

1. **Partial dysautonomia** refers to autonomic impairment in some parts of the nervous system, with efforts by the still-functioning nervous system to compensate. A number of studies have shown findings of distal denervation in POTS patients, including the following:
   (a) Lower extremity anhidrosis.
   (b) Impaired norepinephrine spillover in the legs. The rate of entry of norepinephrine into the femoral vein is reduced in response to hypotensive stimuli.
   (c) A decrease in muscle sympathetic nerve activity recruitment in the legs in response to nitroprusside-induced hypotension.
2. **Increased sympathetic activity.** Studies have shown that patients with POTS have elevated arterial norepinephrine levels and decreased norepinephrine clearance. Some patients also have increased resting heart rates and an exaggerated response to isoproterenol, suggesting adrenoreceptor hypersensitivity.
3. **Hypovolemia.** Studies have shown reduced blood volume and reduced erythrocyte volume. The cause of these findings is not clear, but some have postulated problems with the rennin–angiotensin–aldosterone axis, possibly due to renal denervation.
4. **Changes in venous function.** Patients with POTS have been shown to have increased venous pooling and a decrease in stroke volume on standing.
5. **Primary baroreflex abnormalities** may also cause the increase in heart rate without change in blood pressure that is seen on standing.

B. Diagnosis. There are no established criteria for the diagnosis of POTS. The characteristic finding is an increase in heart rate on tilt table testing or standing. Many centers use an increase in heart rate of > 30 beats per minute or a rise in heart rate to > 120 beats per minute in the first 10 minutes of tilt as their diagnostic criteria. Orthostatic hypotension does not typically occur. There may be an increase in plasma norepinephrine levels (> 600 ng/mL), both with rest and on standing. It is important to rule out other conditions, such as autonomic neuropathy, central dysautonomia, bedrest deconditioning, dehydration, and medication effects that may also cause these findings.

C. Treatment. Because of the heterogeneous etiologies of POTS, which contribute differently to each patient's symptoms, treatment can be very challenging and often requires multiple attempts with different regimens. There are no large controlled studies of therapy.

1. Volume expansion using oral fluid intake, a high salt diet, and the mineralocorticoid fludrocortisone can improve symptoms. This treatment can cause hypertension, fluid retention, and hypokalemia, and patients should be monitored closely.
2. Adrenoreceptor agonists such as midodrine may improve symptoms in patients with mainly peripheral autonomic denervation. Studies have shown improvement in heart rate response and symptoms during tilt testing with these treatments.
3. Patients with mainly hyperadrenergic symptoms may see improvement with β-blockers. In one placebo-controlled, randomized crossover study, low-dose propranolol (20 mg) improved tachycardia and reduced symptoms, but high-dose propranolol (80 mg) did not change or worsened symptoms.
4. Pyridostigmine, an acetylcholinesterase inhibitor, has been used to attenuate tachycardia.
5. Other centrally acting drugs, such as selective serotonin reuptake inhibitors, clonidine, methyldopa, and phenobarbital, have been used with some success, but experience with their use is very limited.

CHAPTER 34

Chetan Vagesh Hampole

Assessing and Managing Cardiac Risk in Noncardiac Surgical Procedures

I. INTRODUCTION

A. Background. Patients undergoing noncardiac surgeries can be at risk for major perioperative cardiac complications, particularly if they are elderly. Worldwide, it is estimated that approximately 500,000 to 900,000 patients per year undergoing noncardiac surgery suffer a perioperative cardiac death, nonfatal myocardial infarction (MI), or nonfatal cardiac arrest. Given the increasingly advanced age of patients undergoing surgeries, this risk is expected to remain substantial. The risk of death from a perioperative MI may be as high as 50%. The elevated risk of perioperative MI is multifactorial and may be primarily due to increased sympathetic tone, a proinflammatory state,

hypercoagulability, and occasional hypoxia during the first few days after surgery. In 1977, Goldman et al. (1) developed a multifactorial index of risk for cardiac morbidity and mortality. Extensive work has subsequently been done on various aspects of perioperative cardiac evaluation, including clinical factors and noninvasive testing. The variety of strategies and practices used has led to high costs associated with preoperative risk assessment. Many studies have recently challenged common practices in the area of perioperative care that were found to have no clear benefit. The American College of Cardiology/American Heart Association (ACC/AHA) Task Force Committee developed practice guidelines aimed at providing a more efficient approach to preoperative evaluation. These guidelines were most recently updated in 2007.

B. Objective. The purpose of preoperative evaluation is not to "clear" patients for an operation. The purpose is to **assess current medical status and cardiac risks posed by the planned operation** and **recommend strategies that may influence short- and long-term outcomes**.

1. Although the preoperative assessment is a complex process, a few **basic questions and observations** by a physician with regard to the patient's general health, functional capacity, cardiac risk factors, comorbid medical illnesses, and type of anticipated operation can assist in evaluating cardiac risk.
2. It is not prudent to order noninvasive tests for every patient. The physician tries to obtain as much information as possible by means of **history and physical examination**. Noninvasive tests are requested only if the results are likely to influence treatment and outcome.
3. **As a general rule, preoperative intervention is rarely needed unless it is indicated irrespective of the preoperative context**. Patients with clinically stable heart disease may not need extensive preoperative testing.
4. Communication is vital among primary physicians, consulting physicians, anesthesiologists, and surgeons for short- and long-term care of patients.

II. CLINICAL PRESENTATION

A. History

1. The clinician needs to identify cardiac conditions that place a patient at increased risk, such as recent MI, decompensated congestive heart failure (CHF), unstable angina, significant arrhythmias, and valvular heart disease.
2. Attention is directed at serious **comorbid conditions** such as diabetes mellitus, peripheral vascular disease, history of stroke, renal disease, and pulmonary disease.
3. **Functional capacity** is determined on the basis of the patient's ability to perform certain daily tasks (Table 34.1).

B. Physical findings. A thorough examination is crucial, and specific findings are addressed.

1. The physical examination includes checking blood pressure in both arms (supine and standing) and evaluation of carotid arterial pulse (character, volume, and upstroke), jugular venous pulsation, cardiac rhythm, heart sounds (murmurs, gallops, or rubs), and extremity pulses.
2. Lung fields are auscultated, and the abdomen is palpated for a possible aneurysm.
3. **High-risk findings** include severe aortic stenosis murmur, elevated jugular venous pressure, pulmonary edema, or S_3 gallop.

C. Indices to predict cardiac risk. Cardiac risk is a function of patient characteristics and the proposed operation.

1. **The Goldman index** was developed in 1977. The index is a score derived from nine independent variables that predict perioperative cardiac events, and each is assigned a point value (Table 34.2).
2. **Detsky et al.** (2) developed a modified multifactorial index to address the severity of coronary artery disease (CAD) and heart failure (Table 34.3).

TABLE 34.1 Estimated Energy Requirements for Various Activities

1 to 4 METs
Eat, dress, or use the toilet
Walk indoors around the house
Walk on level ground at 2 mph (3.2 km/h)
Do light housework such as washing dishes
4 to 10 METs
Climb a flight of stairs
Walk on level ground at 4 mph (6.4 km/h)
Run a short distance
Heavy work such as vacuuming or lifting heavy furniture
Play games such as golf or doubles tennis
More than 10 METs
Participate in strenuous activities such as swimming, singles tennis, basketball, or skiing

MET, metabolic equivalent.

TABLE 34.2 Original Goldman Multifactorial Cardiac Risk Index

Criteria	Points
History	
Age older than 70 y	5
MI in previous 6 mo	10
Physical examination	
S_3 gallop or JVD	11
Significant AS	3
Electrocardiogram	
Rhythm other than sinus or PACs on last preoperative ECG	7
Greater than 5 PVCs/min documented at any time preoperatively	7
General status (one or more of the following)	
$P_{O_2} < 60$ or $P_{CO_2} > 50$ mm Hg, $K < 3.0$ or $HCO_3 < 20$ mEq/L, BUN > 50 or Cr > 3.0 mg/dL; abnormal AST, signs of chronic liver disease, or patient bedridden from noncardiac causes	3
Operation	
Intraperitoneal, intrathoracic, or aortic operation	3
Emergency operation	4
Total	53

(continued)

TABLE 34.2 Original Goldman Multifactorial Cardiac Risk Index (*continued*)

Class	Points	Cardiac deaths (%)
I	0–5	0.2
II	6–12	2.0
III	13–25	2.0
IV	≥ 26	56.0

AS, aortic stenosis; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cr, creatinine; ECG, electrocardiogram; JVD, jugular venous distention; MI, myocardial infarction; PAC, premature atrial contraction; PVC, premature ventricular contraction.

Adapted from Goldman L, Caldera DL, Nussbaum SR, et al. Multifactorial index of cardiac risk in noncardiac surgical procedures. *N Engl J Med.* 1977;297:845–850.

TABLE 34.3 Detsky's Modified Cardiac Risk Index

Variable	Points
Coronary artery disease	
MI within 6 mo earlier	10
MI more than 6 mo earlier	5
Canadian class of angina	
Class III	10
Class IV	20
Unstable angina within 3 mo	10
Alveolar pulmonary edema	
Within 1 wk	10
Ever	5
Valvular disease	
Suspected critical aortic stenosis	20
Arrhythmias	
Sinus plus atrial premature beats or rhythm other than sinus on last preoperative electrocardiogram	5
Greater than five ventricular premature beats at any time before operation	5
Poor general medical status[a]	5
Age older than 70 y	5
Emergency operation	10
Total	120

[a]Defined as any of the following: $P_{O_2} < 60$ mm Hg, $P_{CO_2} > 50$ mm Hg, $K^+ < 3.0$, $HCO_3 < 20$ mEq/L, BUN = 18 mmol/L (> 50 mg/dL), serum Cr > 260 mmol/L (> 2.9 mg/dL), abnormal AST, signs of chronic liver disease, or patient bedridden because of noncardiac causes. AST, aspartate aminotransferase; BUN, blood urea nitrogen; Cr, creatinine; MI, myocardial infarction.

Adapted from Detsky AS, Abrams HB, McLaughlin JR, et al. Predicting cardiac complications in patients undergoing non-cardiac surgery. *J Gen Intern Med.* 1986;1:211–219.

TABLE 34.4 Revised Cardiac Risk Index

Six independent predictors of major cardiac complications
High-risk surgery (intrathoracic, intraperitoneal, or suprainguinal vascular procedures)
History of ischemic heart disease (history of MI or a positive exercise stress test, current complaint of chest pain thought to be due to MI, use of nitrate therapy, or ECG with pathological Q waves; do not count prior coronary revascularization procedure unless one of the other criteria for ischemic heart disease is present)
History of heart failure
History of cerebrovascular disease
Diabetes mellitus requiring insulin therapy
Serum creatinine > 2.0 mg/dL (177 μmol/L)
Rate of cardiac death, nonfatal MI, and nonfatal cardiac arrest according to the number of predictors
No risk factors: 0.4% (95% CI, 0.1–0.8%)
One risk factor: 1.0% (95% CI, 0.5–1.4%)
Two risk factors: 2.4% (95% CI, 1.3–3.5%)
Three or more risk factors: 5.4% (95% CI, 2.8–7.9%)
Rate of cardiac death and nonfatal MI, cardiac arrest or ventricular fibrillation, pulmonary edema, and complete heart block according to the number of predictors and the nonuse or use of β-blockers
No risk factors: 0.4–1.0% versus < 1% with β-blockers
One to two risk factors: 2.2–6.6% versus 0.8–1.6% with β-blockers
Three or more risk factors: > 9% versus > 3% with β-blockers

Adapted from Lee TH, Marcantonio ER, Mangione CM et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation.* 1999;100:1043–1049.

3. In 1999, **Lee et al. (3) developed the Revised Cardiac Risk Index** to simplify the process using only six risk factors (Table 34.4). This is now the most widely used risk index and is the one incorporated in the ACC/AHA guidelines.

D. Clinical assessment of risk factors. Instead of dividing risk factors into major, intermediate, and minor groups, the new 2007 ACC/AHA guidelines adopted a more practical approach by recognizing the following conditions:

1. **Active cardiac conditions.** The presence of one or more of these conditions warrants intensive evaluation and management before proceeding with noncardiac surgery and may result in delay or cancellation of the scheduled surgery (Table 34.5).
2. **Clinical risk factors.** With the exception of the type of surgery, these factors are the same risk factors identified by the Revised Cardiac Risk Index (Table 34.4), and they include the following:
   - **(a)** History of ischemic heart disease
   - **(b)** History of compensated or prior heart failure
   - **(c)** History of cerebrovascular disease
   - **(d)** Diabetes mellitus
   - **(e)** Renal insufficiency
3. The original guidelines recognized a group of **minor** predictors that included advanced age, abnormal electrocardiogram (ECG), rhythm other than sinus, and

TABLE 34.5 Active Cardiac Conditions That Warrant Evaluation and Treatment before Noncardiac Surgery

Unstable coronary syndromes
Acute or recent myocardial infarction[a]
Unstable or severe[b] angina (Canadian class III or IV)[c]
Decompensated heart failure
Significant arrhythmias
High-grade atrioventricular block
Mobitz type II atrioventricular block
Third-degree atrioventricular block
Symptomatic ventricular arrhythmias
Supraventricular arrhythmias (including atrial fibrillation) with uncontrolled ventricular rate
Symptomatic bradycardia
Newly recognized ventricular tachycardia
Severe valvular disease
Severe aortic stenosis (mean pressure gradient ≥ 40 mm Hg, aortic valve area ≤ 1.0 cm^2, or symptomatic)
Symptomatic mitral stenosis

[a]The American College of Cardiology National Database Library defines acute MI as within 7 d and recent MI as > 7 d and ≤ 1 mo.

[b]May include stable angina among patients who are unusually sedentary.

[c]Data from Campeau L. Grading of angina pectoris. *Circulation.* 1976;54:522–523.

Adapted from Fleisher LA, Beckman JA, Brown KA et al. ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Developed in Collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery. *J Am Coll Cardiol.* 2007;50:1707–1732.

uncontrolled hypertension. **Although the presence of many of these factors might lead to a *higher suspicion of CAD,* they have *not* been shown to increase perioperative risk independently, and therefore, they are no longer incorporated into the recommendations for treatment.**

III. TYPE OF OPERATION. In addition to clinical markers and functional capacity, **the proposed operation is an important factor, especially among patients with multiple clinical risk factors** (Table 34.6). The consultant uses all the information available to estimate cardiac risk and provides recommendations to minimize perioperative risk. For **surgical emergencies**, the patient should **proceed directly to the operating room**; emphasis in these circumstances is on postoperative evaluation and management. For **urgent surgical procedures**, evaluation must be **tailored to the underlying disease process**. Elective procedures allow for more thorough evaluation, and all care should be taken to minimize risk. **Testing is limited exclusively to those studies whose results might change management.**

TABLE 34.6 Cardiac Risk Stratification by the Type of Surgical Procedure

High-risk procedure (cardiac risk > 5%)
Aortic and other major vascular surgery (endovascular abdominal aortic aneurysm repair is considered intermediate risk) and peripheral vascular surgery (carotid endarterectomy is considered intermediate risk)
Intermediate-risk procedure (cardiac risk 1–5%)
Carotid endarterectomy and endovascular abdominal aortic aneurysm repair
Head and neck surgery
Intraperitoneal surgery
Intrathoracic surgery
Orthopedic surgery
Prostate surgery
Low-risk procedure (cardiac risk < 1%)
Breast surgery
Cataract surgery
Endoscopic procedures
Superficial procedures
Ambulatory surgery

Adapted from Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Developed in Collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery. *J Am Coll Cardiol*. 2007;50:1707–1732.

IV. SUPPLEMENTAL PREOPERATIVE EVALUATION

A. Routine laboratory tests such as serum creatinine, hemoglobin, platelets, potassium, liver profile, and oxygen saturation are important in determining whether a patient needs special attention. Such patients include those with bleeding risk, renal failure, or liver disease.

B. Patients with **pulmonary disease** (i.e., chronic obstructive pulmonary disease or pulmonary fibrosis) undergo a preoperative **arterial blood gas evaluation**.

C. A 12-lead **ECG** is recommended for patients with at least one clinical risk factor who are undergoing vascular surgery and for patients with known history of CAD, peripheral vascular disease, or cerebrovascular disease who are undergoing an intermediate-risk surgical procedure. A 12-lead ECG is also reasonable in patients with no clinical risk factors who are undergoing vascular surgery and, possibly, in patients with at least one clinical risk factor who are undergoing intermediate-risk surgery.

D. Echocardiography. Echocardiograms can provide information about certain pathologic conditions (left ventricular dysfunction and aortic stenosis) that predispose to increased perioperative cardiac risk. However, the routine use of echocardiography is not helpful and should be reserved for patients who meet ACC/AHA clinical guidelines or for patients in whom the physical examination is suggestive of aortic stenosis, regardless of the planned surgery.

V. STEPWISE APPROACH TO PREOPERATIVE CARDIAC ASSESSMENT. The ACC/AHA Task Force developed an **algorithm for preoperative cardiac evaluation** to help physicians systematically identify clinical predictors and determine if noninvasive testing is indicated prior to the noncardiac surgery (Fig. 34.1).

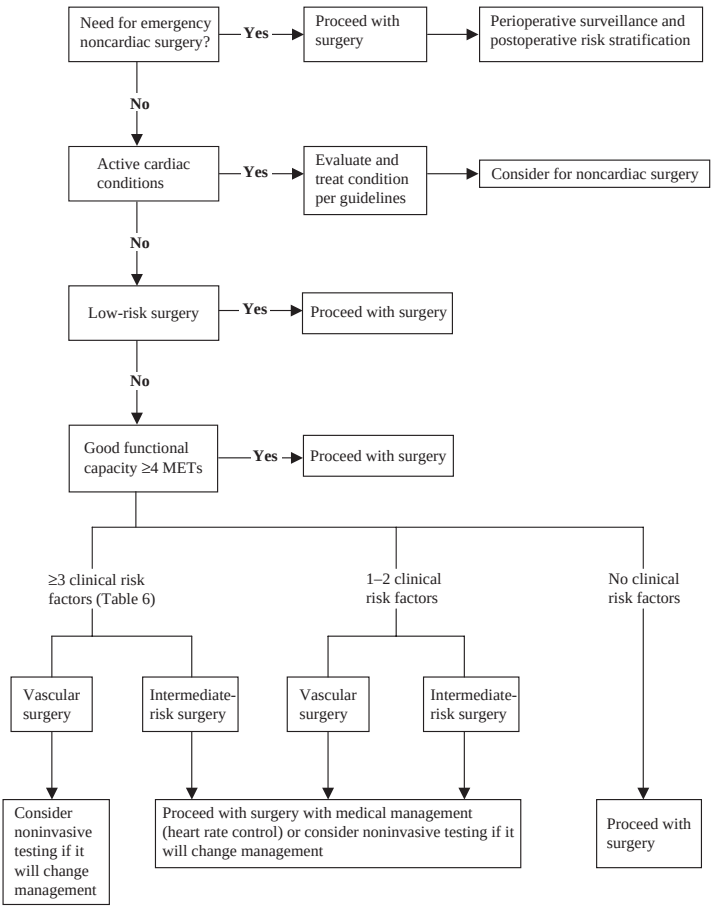

FIGURE 34.1 A stepwise approach to preoperative cardiac evaluation of a patient undergoing a noncardiac surgery. (Adapted from Fleisher LA, Beckman JA, Brown KA, et al. ACC/AHA 2007 Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery). Developed in Collaboration with the American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, and Society for Vascular Surgery. *J Am Coll Cardiol*. 2007;50:1707–1732.)

VI. NONINVASIVE CARDIAC STRESS TESTING. The ability of noninvasive cardiac tests to predict perioperative risk is uncertain. Recently, there has been increasing evidence discouraging the need for their routine use in patients undergoing preoperative evaluation. This shift away from noninvasive testing was supported by the results of a randomized controlled trial of preoperative myocardial revascularization in vascular surgery patients that showed no improvement in perioperative or long-term outcomes associated with prophylactic revascularization. Another study challenged the old ACC/AHA guidelines by randomizing stable intermediate-risk patients undergoing major vascular surgery between cardiac stress testing strategy and no testing. By using excellent β-blocker therapy with tight heart rate control of 60 to 65 beats/min, there was no significant difference in the primary end point (composite postoperative cardiac death and/or nonfatal MI) between preoperative cardiac testing and no testing strategies. Therefore, **preoperative noninvasive cardiac testing should be reserved for patients who are candidates for these tests according to guidelines and who based on the results of these tests could potentially be considered for angiography and revascularization regardless of the planned surgery**.

These findings were reflected in the new ACC/AHA 2007 guidelines:

(A) Patients with **active** cardiac conditions (Table 34.5) should be **evaluated and treated before noncardiac surgery** (class I).

(B) In patients with **poor (< 4 metabolic equivalents of the task) or unknown functional capacity**, who have **three or more clinical risk factors** and are undergoing **vascular surgery**, noninvasive **testing is reasonable if it will change management** (class IIa).

(C) In patients with poor or unknown functional capacity who have one to two clinical risk factors and who are undergoing intermediate-risk surgery, noninvasive testing may be considered (class IIb).

(D) In patients with good functional capacity who have one to two clinical risk factors and who are undergoing vascular surgeries, noninvasive testing may be considered (class IIb).

(E) Noninvasive testing is **not** useful in patients ***without*** clinical risk factors who are undergoing **intermediate-risk surgery**.

(F) Noninvasive testing is not useful in patients who are undergoing low-risk surgery.

There are **different modalities for stress testing,** including exercise ECG, exercise or pharmacologic nuclear stress testing, and exercise or pharmacologic stress echocardiography. When ordering these tests, **it is important to remember the following**:

(A) When feasible, **exercise is the modality of choice** for stress testing because it provides an objective assessment of functional capacity. Pharmacologic stress testing (adenosine, dipyridamole, and dobutamine) should be reserved for patients who cannot exercise.

(B) Exercise and pharmacologic stress testing have **excellent negative predictive values** (90% to 100%) **but poor positive predictive values** (6% to 67%), meaning that although a negative study is reassuring, a positive one is still a relatively weak predictor of a perioperative cardiac event.

(C) Intravenous dipyridamole and adenosine should be avoided in patients with significant bronchospasm or critical carotid artery stenosis.

(D) Dobutamine should be avoided in patients with significant arrhythmias, severe hypertension, or hypotension.

(E) Stress echocardiography (exercise or dobutamine) offers the advantage of providing additional information about ventricular and valvular function.

VII. PREOPERATIVE CORONARY REVASCULARIZATION. The original ACC/AHA guidelines state that the indications for revascularization before noncardiac surgery should be similar to those in the general population. In other words, there is **no evidence to**

support the role of "prophylactic" preoperative revascularization, and the decision to pursue revascularization should be the same regardless of the planned surgery. However, these statements have been based on expert opinion, and there has been substantial variability among clinicians concerning general practice with cardiac revascularization preoperatively. **The Coronary Artery Revascularization Prophylaxis (CARP) trial** was the first large randomized trial that addressed this issue. It randomized 510 patients with established CAD, who were deemed to be at high risk for perioperative cardiac complications, to undergo either revascularization (percutaneous coronary intervention [PCI] or coronary artery bypass grafting [CABG]) or no revascularization before elective major vascular surgery. After a median follow-up of 2.7 years, the death rates were the same in both groups. Even among the subsets of patients who were considered to be at especially high risk according to imaging results or by the Revised Cardiac Risk Index, there were no differences in outcomes between the two groups. Although the study was not designed to test short-term benefit of prophylactic revascularization, there was also no reduction in early postoperative cardiac complications.

Patients who undergo **PCI** represent a clinical challenge in terms of managing their antiplatelet therapy at the time of noncardiac surgery. Premature discontinuation of antiplatelet therapy (aspirin and clopidogrel) carries the risk of in-stent thrombosis. **Bare metal stent (BMS)** thrombosis is most common in the first 2 weeks after stent placement and is very rare after 4 weeks due to rapid endothelialization. On the other hand, there has been growing concern that drug-eluting stent **(DES)** carries greater risk for in-stent thrombosis compared with BMS. The optimal period to delay noncardiac surgery after the use of DES remains unclear.

A. The **indications for revascularization (CABG or PCI) before noncardiac surgery should be similar to those in the general patient population irrespective of the planned surgery:**
   (1) Stable angina with known left main disease
   (2) Stable angina with three-vessel disease (especially with ejection fraction [EF] < 50%)
   (3) Stable angina with two-vessel disease with significant proximal left anterior descending artery stenosis and either EF < 50% or ischemia on noninvasive testing
   (4) High-risk unstable angina or non–ST-segment elevation MI
   (5) Acute ST-elevation MI

B. Patients with **asymptomatic ischemia** (based on functional study) do not appear to benefit from preoperative revascularization prior to noncardiac surgeries.

C. Routine prophylactic revascularization should not be performed in patients with stable CAD before noncardiac surgery.

D. Small observational studies suggest that patients who undergo **CABG** should wait for at least 4 weeks before proceeding with noncardiac surgery.

E. Patients who undergo **balloon angioplasty without stenting** should wait for **at least 2 to 4 weeks** before proceeding with elective noncardiac surgery to allow adequate time for healing of the injured vessel. Daily aspirin should be continued whenever possible. The risk of stopping aspirin should be weighed against the benefit of reducing bleeding risk from surgery. Balloon angioplasty without the use of stent might provide a temporary bridge to go through noncardiac surgery with the intention of implanting stents after the surgery.

F. Among patients who undergo stenting with **BMSs**, it is safer to **wait for 6 to 8 weeks** on dual antiplatelet therapy (aspirin and clopidogrel) before proceeding with surgery to avoid the risk of in-stent thrombosis with premature discontinuation of antiplatelet therapy. After 4 to 6 weeks, clopidogrel could be stopped preoperatively, ideally 5 to 7 days before the noncardiac surgery. Daily aspirin use should be continued unless the risk of bleeding outweighs the benefit of continuing aspirin therapy.

G. Among patients who undergo stenting with the **DES**, the optimal duration for dual antiplatelet therapy is not well defined, but should be **at least 12 months**. Elective

noncardiac surgery that requires discontinuation of clopidogrel, or both clopidogrel and aspirin, should be delayed. In general, if noncardiac surgery is expected within the next 12 months, the physician should strongly consider avoiding the use of DES. BMS or balloon angioplasty might provide an alternative approach.

H. Perioperative management of patients with prior PCI undergoing unplanned surgery

1. The ideal waiting time before proceeding with noncardiac surgery should be at least
   (a) 2 to 4 weeks for balloon angioplasty,
   (b) 4 to 6 weeks for BMS, and
   (c) 12 months for DES.
2. For patients who need noncardiac surgery that falls within the time frame that requires dual antiplatelet therapy and cannot be delayed, strong consideration should be given to continuation of dual antiplatelet therapy whenever possible.
3. If the risk of bleeding with dual antiplatelet therapy outweighs the benefit, serious consideration should be given to continuation of at least aspirin whenever possible. Clopidogrel should be resumed as soon as possible after surgery.

I. It is important to recognize that **the recommended time frames for dual antiplatelet therapy are arbitrary and based on expert opinion**. These cases should be addressed individually with good communication between the cardiologist, anesthesiologist, and the surgeon. **Certain conditions might require longer dual antiplatelet therapy** (e.g., left main stenting, history of stent thrombosis, multivessel stenting, and stenting of the only remaining coronary artery or bypass graft).

Because of the lack of prospective studies as well as guidelines, there are a wide variety of potential approaches to the perioperative management of patients with stents taking dual antiplatelet therapy. The ACC/AHA/SCAI/ACS/ADA Science Advisory Panel notes the importance of 12 months of dual antiplatelet therapy after placement of a DES and educating the patient about the hazards of premature discontinuation. Therefore, management should be carried out on a case-by-case basis. Major factors that should be considered are surgical hemorrhagic risk and the thrombotic risk of the stent.

VIII. MANAGEMENT OF SPECIFIC PREOPERATIVE CONDITIONS

A. Valvular heart disease. In general, the indications for evaluation and treatment of valvular heart disease are similar to those in the nonpreoperative setting. Symptomatic stenotic lesions are associated with increased perioperative morbidity, whereas symptomatic regurgitant valve diseases can usually be managed medically and with close monitoring perioperatively.

1. Critical **aortic stenosis** must be recognized promptly and, if symptomatic, should be managed with valve replacement or, for selected patients, valvuloplasty as a short-term bridge through noncardiac surgery.
2. **Mitral stenosis** when mild and asymptomatic is managed medically with heart rate control. When mitral stenosis is severe and symptomatic, mitral valvuloplasty or valve replacement is considered before a high-risk operation is performed.
3. For patients with **aortic or mitral regurgitation,** the medical regimen is optimized with diuretics and afterload reduction.
4. Appropriate **prophylaxis for bacterial endocarditis** is administered for patients with valvular disorders according to the guidelines.
5. Patients with **prosthetic valves who need oral anticoagulation** can usually safely undergo minimally invasive procedures such as dental work or skin biopsy if the international normalized ratio is briefly reduced to a low or

subtherapeutic range. Full anticoagulation is resumed after the procedure. For patients undergoing extensive surgical procedures with prosthetic valves, intravenous unfractionated heparin therapy is initiated. Heparin can be reserved for the following patients:

(a) those with recent thromboembolic events (< 1 year);
(b) those with mechanical valve in the mitral position;
(c) those with a history of thromboembolism while not on anticoagulation
(d) those with Bjork-Shiley or Starr-Edwards valve; and
(e) those with three or more of the following risk factors (atrial fibrillation [AF], previous thromboembolism, hypercoagulable condition, mechanical prosthesis, and left ventricular EF < 30%).

Mechanical valves in the mitral position are usually more thrombogenic and, therefore, require a lower threshold for heparin conversion. The use of low-molecular-weight heparin may provide an alternative approach for anticoagulation, but is still controversial as valve thrombosis has been reported with its use. Oral anticoagulants are resumed as soon as possible after the procedure.

B. Arrhythmias. The ACC/AHA 2007 guidelines recognize **high-grade atrioventricular block, symptomatic bradycardia, symptomatic or newly recognized ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate, and symptomatic bradycardia as active cardiac conditions that require further evaluation before proceeding with noncardiac surgery**. The following points are important to remember while evaluating arrhythmias in the preoperative setting:

1. Identification of any **underlying cardiac disease, drug toxicity, or metabolic disturbances** that could be the cause of the arrhythmia is very important.
2. For symptomatic and hemodynamically significant arrhythmias, therapy should target the underlying cause and then the arrhythmia itself.
3. The indications for antiarrhythmic therapy and cardiac pacing are similar to those in nonoperative setting.
